Wavelet Domain Image Restoration Using Edge Preserving Prior Models

Murat Belge and Eric L. Miller
235 Forsyth Building
Northeastern University
Boston, MA 02115

Abstract

In this paper we consider a wavelet-based edge preserving regularization scheme for use in linear image restoration problems. Our efforts build on a collection of mathematical results indicating that wavelets are especially useful for representing functions that contain discontinuities (i.e. edges in two dimensions or jumps in 1D). We interpret the resulting theory in a statistical signal processing framework and obtain a highly flexible framework for adapting the degree of regularization to the local structure of the underlying image. In particular, we are able to adapt quite easily to scale-varying and orientation-varying features in the image while all the time retaining the edge preservation properties of the regularizer. We demonstrate an efficient algorithm for obtaining the reconstructions from observed data and for choosing the multiple regularization parameters governing the priors.

1 Introduction

In this work, we consider the problem of recovering an unknown image \mathbf{x} from measurements \mathbf{y} where the two are related via

$$\mathbf{y} = \mathbf{H}\mathbf{x} + \mathbf{n} \quad (1)$$

with \mathbf{H} a known matrix defining the linear degradation, \mathbf{x} and \mathbf{y} vectors representing lexicographically ordered pixels in the original and degraded images and \mathbf{n} representing additive white Gaussian noise (i.e. $\mathbf{n} \sim N(0, \sigma^2 \mathbf{I})$). The above problem is typically ill-posed in the sense that the operator \mathbf{H} may not be invertible or it may be ill-conditioned. In such a case, the original problem is replaced by a well conditioned one whose solution approximates that of the original. This is usually achieved by incorporating some *a priori information* about the original image.

In the stochastic interpretation of image restoration, the prior information on the image \mathbf{x} can be expressed in the form of an *a priori* probability distribution $P(\mathbf{x}|\boldsymbol{\theta})$ which is assumed to be dependent on a set of parameters $\boldsymbol{\theta}$. Bayes rule allows us to combine the prior information with the information contained

in the data to obtain the *a posteriori* distribution

$$P(\mathbf{x}|\mathbf{y}, \sigma, \boldsymbol{\theta}) = \frac{P(\mathbf{y}|\mathbf{x}, \sigma)P(\mathbf{x}|\boldsymbol{\theta})}{P(\mathbf{y})} \\ \propto \exp \left\{ -\frac{1}{2\sigma^2} \|\mathbf{y} - \mathbf{H}\mathbf{x}\|_2^2 - \Phi(\mathbf{x}, \boldsymbol{\theta}) \right\} \quad (2)$$

where the prior distribution on \mathbf{x} is assumed to be proportional to $\exp\{-\Phi(\mathbf{x}, \boldsymbol{\theta})\}$. Conventional prior distributions are typically expressed as, $\exp\{-\frac{1}{2\sigma^2} \|\mathbf{L}\mathbf{x}\|_2^2\}$, which is equivalent to the assumption that \mathbf{x} is coming from a Gaussian distribution with covariance matrix $(\mathbf{L}^T \mathbf{L})^{-1}$. The restored image \mathbf{x}^* is then found by maximizing the posterior probability with respect to \mathbf{x} , i.e

$$\mathbf{x}^*(\boldsymbol{\theta}, \sigma) = \arg \min_{\mathbf{x}} \frac{1}{2\sigma^2} \|\mathbf{y} - \mathbf{H}\mathbf{x}\|_2^2 + \Phi(\mathbf{x}, \boldsymbol{\theta}). \quad (3)$$

The quality of the restoration depends on both the form of the prior (i.e. form of $\Phi(\cdot)$ in (3)) and the choice of hyperparameters $(\boldsymbol{\theta}, \sigma)$.

In this paper, we consider a Bayesian image restoration algorithm in which the desired image's subbands are modeled as stationary generalized Gaussian processes. The intuition underlying our modeling is that images typically have spatial structure consisting of smooth areas dispersed with occasional edges. When the image is subjected to a subband decomposition, band pass and high pass pixels of the image are seen to have significantly non-Gaussian behavior with a distribution function sharply peaked about zero (contributions coming from smooth areas) and heavy tails which are mainly due to the edges [5]. Gaussian modeling puts too much penalty on the sharp transitions (edges) in the image therefore the restorations based on Gaussian modeling look smooth. Several authors used generalized Gaussian distributions to model subband statistics in the context of image coding and denoising. However, to our knowledge such models have not been used in connection with image restoration yet. In this paper, we develop new multiresolution edge preserving image models for image restoration applications and solve the nonlinear optimization and parameter selection issues associated with the new modeling.

2 Wavelet Transform of Images

The wavelet transform is a time-frequency representation which has good localization in both domains. We restrict our attention to orthonormal separable wavelet transforms and assume that the reader is familiar with the wavelet theory [1]. The following discussion is intended to establish the notation that will be used in the rest of the paper.

Following the wavelet literature, elements of the image $x(m, n)$, $1 \leq m, n \leq 2^J$, are called the finest scale scaling coefficients. From these finest scale scaling coefficients we obtain the scaling coefficients at a lower resolution level which represent a coarser scale version of x and a set of wavelet coefficients which represents the horizontal, vertical and diagonal details lost in moving from a finer scale to a coarser scale. By repeating this procedure on the coarse scale coefficients $k-1$ times, we can obtain a k -level wavelet decomposition. We denote the scaling coefficients at scale j_0 and position (m, n) by $x_{j_0,0}(m, n)$, $1 \leq m, n \leq 2^{j_0}$ and the wavelet coefficients at scale j , $j_0 \leq j \leq J-1$, orientation i , $1 \leq i \leq 3$ and position (m, n) by $x_{j,i}(m, n)$.

The wavelet transform can be represented as an orthonormal matrix \mathcal{W} , which transforms an image \mathbf{x} into its wavelet domain representation through matrix multiplication. That is, $\hat{\mathbf{x}} = \mathcal{W}\mathbf{x}$. By using this, (1) can be transformed into wavelet domain as

$$\begin{aligned}\mathcal{W}\mathbf{y} &= (\mathcal{W}\mathcal{H}\mathcal{W}^T)\mathcal{W}\mathbf{x} + \mathcal{W}\mathbf{n} \\ \hat{\mathbf{y}} &= \hat{\mathbf{H}}\hat{\mathbf{x}} + \hat{\mathbf{n}},\end{aligned}\quad (4)$$

where $\mathcal{W}^T\mathcal{W} = \mathbf{I}$ follows from the orthonormality of the wavelet transformation.

3 A Multiscale Image Model for Use in Image Restoration

Following the work in [5] on image coding and denoising, we model the distribution of wavelet coefficients of images by a Generalized-Gaussian (GG) density [9]. The following distribution function serves as the prior model

$$P(x_{j,i}(m, n)|p, \theta_{j,i}(m, n)) \propto \exp \left\{ -\frac{1}{p} \left| \frac{x_{j,i}(m, n)}{\theta_{j,i}(m, n)} \right|^p \right\}, \quad (5)$$

where $1 \leq p \leq 2$ is a parameter which determines the tail behavior of the density function and $\theta_{j,i}(m, n)$ is the *scale parameter* similar to the variance of a Gaussian density. For simplicity, we will refer to the density in (5) as $GG(0, \theta_{j,i}(m, n), p)$. For $p = 1$ we have the Laplacian or double exponential density and for $p = 2$ we have the familiar Gaussian density. Intermediate values of p correspond to increasingly heavier tails. We assume that the scaling coefficients $x_{j_0,0}$, $1 \leq m, n \leq 2^{J-L}$, are i.i.d. with $GG(0, \theta_{j_0,0}(m, n), p)$ density.

The specification of one θ parameter for every wavelet coefficient results in an image model far too complex to be of use in a restoration procedure. Generally, there is neither sufficient information *a priori* nor in the data to reliably specify or estimate a

model with as many degrees of freedom as unknowns in the original image. Nonetheless, the structure of the model in (5) coupled with the specification of the problem in the wavelet domain does suggest a variety of simplifications which are of use for the restoration problem. In this work, we consider the following three:

1. **Model 1:** The variance of the wavelet coefficients decreases exponentially with the scale, i.e., $x_{j,i}(m, n) = GG(0, \theta 2^{-\alpha(j-j_0)}, p)$, $i = 1, 2, 3$, $1 \leq m, n \leq 2^j$ with j_0 the coarsest scale, θ the scale parameter corresponding to j_0 and $\alpha \geq 0$. The rationale behind this model is that it is equivalent to a deterministic modeling of the image as a member of Besov spaces [1].
2. **Model 2:** Scaling coefficients are i.i.d. with $GG(0, \theta_{j_0,0}, p)$ distribution and wavelet coefficients at a particular scale are i.i.d. with $GG(0, \theta_j, p)$, $j = J-L, \dots, J-1$. This model is useful in cases where the variance of the wavelet coefficients at different scales can not be well-approximated by a simple exponential law.

For the remainder of this paper, we assume that the two parameters α and p in the above models are known and fixed *a priori*. Generally, the performance of the regularizer is impacted to a greater extent by the on-line identification of the θ parameters and it is here where we choose to concentrate our efforts.

4 A Multiscale Bayesian Image Restoration Algorithm

Motivated by the above discussion, we consider a restoration scheme for obtaining an estimate of the image's wavelet coefficients $\hat{\mathbf{x}}^*$ which is defined in terms of the following optimization problem:

$$\begin{aligned}\hat{\mathbf{x}}^* &= \arg \min_{\hat{\mathbf{x}}} \{ \|\hat{\mathbf{y}} - \hat{\mathbf{H}}\hat{\mathbf{x}}\|_2^2 + \lambda_{j_0,0} \|\hat{\mathbf{x}}_{j_0,0}\|_p^p \\ &\quad + \sum_j \sum_i \lambda_{j,i} \|\hat{\mathbf{x}}_{j,i}\|_p^p \},\end{aligned}\quad (6)$$

where the notation $\hat{\mathbf{x}}_{j,i}$ denotes the vector of wavelet (scaling) coefficients at scale j and orientation i and $\lambda_{j,i} = \frac{2\sigma^2}{p\theta_{j,i}}$. The cost function in (6) has a unique minimum for a given $\boldsymbol{\lambda}$. This follows from the fact that it is just the summation of an L^2 and an L^1 norm which are both convex in $\hat{\mathbf{x}}$. The first order conditions that must be satisfied by $\hat{\mathbf{x}}^*$ is found by differentiating (6) with respect to $\hat{\mathbf{x}}$. However, the cost function in (6) is not differentiable in its current form due to the fact that the l_p norm term present in the cost function is not differentiable at zero. To alleviate this problem, we slightly perturb the l_p norm term to obtain a differentiable approximation: $\|\mathbf{x}\|_p^p \approx \sum_i (x_i^2 + \beta)^{p/2}$, where x_i is the i th element of the vector \mathbf{x} and $\beta > 0$ is a small constant. Substituting this approximation into (6) and differentiating with respect to $\hat{\mathbf{x}}$ we obtain

Figure 1: Curvature of the L-hypersurface and the corresponding RMSE plot.

the following equation

$$\mathbf{D} = \text{diag} \left[\frac{\lambda_{j,i}}{(|\hat{x}_{j,i}^*(m,n)|^2 + \beta)^{1-p/2}} \right] \quad (7)$$

$$\left(\hat{\mathbf{H}}^T \hat{\mathbf{H}} + \frac{p}{2} \mathbf{D} \right) \hat{\mathbf{x}}^* = \hat{\mathbf{H}}^T \hat{\mathbf{y}} \quad (8)$$

An iterative algorithm based on (8) can be developed to approximate the solution $\hat{\mathbf{x}}^*$. Starting from an initial estimate $\hat{\mathbf{x}}^{(0)}$, we solve the following equation for $\hat{\mathbf{x}}^{(k+1)}$ until convergence is achieved

$$\left(\hat{\mathbf{H}}^T \hat{\mathbf{H}} + \frac{p}{2} \mathbf{D}^{(k)} \right) \hat{\mathbf{x}}^{(k+1)} = \hat{\mathbf{H}}^T \hat{\mathbf{y}}, \quad (9)$$

where $\mathbf{D}^{(k)}$ denotes the diagonal matrix obtained by replacing \hat{x}^* in (7) by $\hat{x}^{(k)}$. It can be shown that the iterative algorithm in (9) converges to the unique minimum of the perturbed cost function in (6). The stabilization constant β affects the convergence rate. The bigger the β , the faster the convergence. However, using a relatively large β has the side effect of smoothing out the edges in the image. Therefore, β should be set to balance the compromise between the convergence rate of the algorithm and sharpness of the resulting solution. Based on our experience, we recommend $\beta \approx 1$ for problems involving real life images.

4.1 Determination of Regularization Parameters

A noteworthy feature of the multiscale image restoration algorithm introduced in the previous section is the need for multiple regularization parameters. In this paper, we utilize a multidimensional extension of the popular L-curve method [7] called the ‘‘L-hypersurface’’ to determine multiple regularization parameters appearing in (6).

The L-hypersurface is a plot of the log of residual norm, $\|\mathbf{y} - \mathbf{H}\mathbf{x}^*(\boldsymbol{\lambda})\|_2^2$, against the log of side constraint norms $\|\hat{\mathbf{x}}_{j,i}^*(\boldsymbol{\lambda})\|_p^p$, $j_0 \leq j \leq J-1$, for a range of regularization parameters. It has been argued and shown through numerical experiments that the points on the L-hypersurface where the Gaussian curvature reaches

a local maxima are closely tied to the points on the restoration error, $\|\mathbf{x} - \mathbf{x}^*(\boldsymbol{\lambda})\|_2^2$, hypersurface where the restoration error reaches a local minima. The L-hypersurface selection for $\boldsymbol{\lambda}$ corresponds to that $\boldsymbol{\lambda}$ for which the Gaussian curvature of the L-hypersurface is a maximum. Monte Carlo simulations indicates that [8] the L-hypersurface method produces regularization parameters which are almost as good as the optimal (i.e. minimizing the restoration error). The necessary formulas for the computation of Gaussian curvature of the L-hypersurface for the problem in (6) are provided in [8].

5 Simulation Study

In this section, we illustrate the performance of our proposed multiscale image restoration algorithm for both real and synthetic images. In the first example, we used a 2-D Gaussian convolutional kernel, with $\sigma_x = \sigma_y = 2.0$ to blur 256×256 Mandrill image. Zero mean white Gaussian noise was added to set the SNR to 30dB. The top two plots in Figure 2 display the original and the blurred, noisy images.

We restored the degraded Mandrill image using three regularization techniques: our proposed multiscale regularization scheme, the Constrained Least Squares (CLS) algorithm with a 2-D Laplacian regularizer [3], and the TV algorithm [6]. The relevant regularization parameters were determined using either the L-curve or the L-hypersurface method. For the TV algorithm and our algorithm we used $\beta = 1.0$ as the stabilization constant. For our multiscale image restoration algorithm, we used the Daubechies eight tap most symmetrical wavelets [2].

In Figure 2 we display the restored Mandrill images. For our multiscale image restoration method we computed two restorations according to the regularization schemes Model 1 and Model 2 described in section 3 with $p = 1.0$. For Model 1, we used a 5-level wavelet decomposition and set the exponential parameter to $\alpha = 1.2$. For Model 2, we used a 3-level wavelet decomposition and set the regularization for the scaling coefficients to 10^{-5} . For the Model 1 case the L-hypersurface was used to determine two parameters corresponding to the scaling coefficients and the coarsest scale wavelet coefficients. In this case, L-hypersurface is a 2-D function of regularization parameters as seen in Figure 1. Also shown in Fig. 1 is a plot of the root mean square error (RMSE), $\sqrt{\frac{1}{N^2} \|\mathbf{x} - \hat{\mathbf{x}}^*\|_2^2}$, as a function of these regularization parameters. Examining these images shows that the L-surface has a distinct extended maxima along which the RMSE is very close to being a minimum. Thus, we see that the restoration algorithm is not overly sensitive to the scaling coefficient regularization parameter and locating the correct regularization parameter for the wavelet coefficients is more important.

In Model 2 restoration, we employed a 3-level wavelet decomposition and assumed that each scale gets a different regularization parameter. Based on the insensitivity of the restoration to the scaling coefficient regularization parameter we set this value to 10^{-5} .

Figure 2: Original, blurred, restored by CLS, restored by TV and restored by Model 1 and Model 2 techniques.

Fig. 2 shows that both the TV algorithm and our algorithm produce restored images visually superior to the CLS algorithm. We also observe that the images restored by our algorithm are a little sharper than that of the TV and the texture-like regions abundant in the Mandrill image (eg. the hairs around the mouth of the Mandrill) are better preserved by our algorithm. The RMSE values are 23.73 for the TV algorithm, 24.11 for the CLS algorithm and 23.75 and 23.84 for the Model 1 and Model 2 restorations respectively. Finally, for this image we see little difference either in terms of the error norm or in terms of visual quality between the the restorations using our method. The primary advantage of the Model 2 approach is that we no longer need to independently set the α parameter.

In our final example, we first blurred the original Bridge image with a 9×9 uniform motion blur and added white Gaussian noise to the degraded image

Figure 3: Original, blurred, restored by the TV, restored by Model 1 scheme.

to set the SNR at 40dB. Figure 4 shows the original and the degraded images. We display the restorations obtained by the TV and the proposed algorithm in Figure 4. For our restoration, we applied the Model 1 regularization scheme with $\alpha = 1.2$, $p = 1.2$ and a 5-level wavelet decomposition. We used the appropriated 2-D L-hypersurface to determine the relevant regularization parameters. Although, in this case the RMSE values were similar (19.43 for TV and 19.72 for the multiscale algorithm), the two restored images in Figure 4 exhibit vastly different visual characteristics. The TV algorithm completely wipes out the small features in the image and produces an overly homogenized restoration resembling an “oil painting” of the original scene. On the other hand, the wavelet-based algorithm is able to reproduce finer detail thereby yielding a more visually appealing restoration.

6 Summary and Conclusions

In this paper, we introduced a wavelet domain multiscale image restoration algorithm for use in linear

Figure 4: Original, blurred, restored by the TV, restored by Model 1 scheme.

image restoration problems. Following the recent results in the area of image denoising and coding, we developed a statistical prior model for the wavelet coefficients of images. Our priors are able to capture spatial, scale space characteristics of images accurately. We developed an efficient iterative optimization algorithm to solve the nonlinear optimization problem resulting from using such priors and introduced the L-hypersurface method to choose the multiple hyperparameters governing the structure of our priors. Comparison of our multiscale image restoration algorithm with either the traditional image restoration algorithms or the more recent edge-preserving image restoration algorithms shows that our algorithm can produce restorations which are visually significantly better than that of the traditional techniques and at least comparable, if not better, than that of the edge-preserving algorithms.

Abstract — Estimation and decision-theoretic methods are presented for the localization and characterization of an object positioned in the interior of a region given sparse, noisy observations of scattered radiation obtained at the surface. Using a B-spline model for the perimeter of the object, a sequential generalized likelihood ratio approach is used to deform the contour, add and remove knots, and determine the internal structure of the object. Prior models on the structure of the object are introduced to regularize the overall problem. Examples are provided for a linearized inverse scattering problem.

I. OVERVIEW

The problems of image formation and target identification from limited observations of scattered wavefields arises in areas such as non-destructive testing, medical imaging, and land-mine remediation. Often the physical quantity of interest (electrical conductivity, acoustic velocity etc.) is pixelated and a gradient decent approach based on the scattering physics is used to find an image of the parameter [1]. The resulting image is then post-processed to extract the desired targets. To bypass the computational burden and ill-posedness of this imaging approach, there has also been much work on directly estimating target shape and location information [2]. The underlying assumption is that the target represents a homogeneous perturbation on a homogeneous background.

Here, we discuss an alternate method designed to solve simultaneously the image formation and object detection problems. The unknown is modeled as a superposition of a slowly varying, compactly supported perturbation on a background of partially known structure. Mathematically, we have

$$g(\mathbf{r}) = S(\mathbf{r})\mathbf{B}_1(\mathbf{r})\mathbf{a}_1 + (1 - S(\mathbf{r}))\mathbf{B}_2(\mathbf{r})\mathbf{a}_2 \quad (1)$$

where g is the object of interest, $S(\mathbf{r})$ is 1 over the (unknown) support of the object and 0 elsewhere, \mathbf{B}_1 (\mathbf{B}_2) are row vectors holding expansion functions describing the texture of the object (background), and \mathbf{a}_1 (\mathbf{a}_2) are the associated expansion coefficients. Assuming the \mathbf{B}_i are

known, the objective of the problem is to determine the structure of S and the \mathbf{a}_i given a data vector y related to g via $y = Ag + n$ where A is the forward scattering operator (here taken to be linear) and n is a vector of additive white Gaussian noise.

We use an iterative algorithm to solve the target id and imaging problems. First, given an estimated perimeter curve at step k (denoted \hat{S}^k), we employ estimation theoretic methods to determine a low-order, optimal image of the perturbation and background. That is, we take as estimates of the \mathbf{a}_i at step k ,

$$(\hat{\mathbf{a}}_1^k, \hat{\mathbf{a}}_2^k) = \arg \min_{\mathbf{a}_1, \mathbf{a}_2} \|y - Ag(\mathbf{a}_1, \mathbf{a}_2, \hat{S}^k)\|_2^2 + \Omega_a(\mathbf{a}_1, \mathbf{a}_2)$$

where $\Omega_a(\mathbf{a}_1, \mathbf{a}_2)$ is derived from a prior statistical model on the behavior of the perturbation and the background. Second, given an estimated image, we use an M-Ary hypothesis testing approach to determine how best to modify the structure of the perimeter curve. The m th hypothesis, H_m^k , is of the form $S_m^k = \hat{S}^k + \delta S_m$ where δS_m is generated by perturbing the current estimate of the object support either by moving a control point in the representation of the boundary or by adding a new knot to this representation. The new curve then is defined by the following

$$\hat{S}^{k+1} = \arg \max_m \left[\log \text{Prob}(y | H_m^k, \hat{\mathbf{a}}_1^k, \hat{\mathbf{a}}_2^k) + \Omega_S(S_m^k) \right]$$

where Ω_S is obtained from a prior model on the structure of S which is constructed to reflect our expectations concerning the geometric properties of the “blobs” likely to be found in the application of interest.

In the talk accompanying this abstract we describe in greater detail the prior models associated with Ω_a and Ω_S , the methods for determining $\hat{\mathbf{a}}_i$, and the manner in which the H_m^k are generated. Finally, we present examples of this algorithm applied to a medical imaging problem in which diffused photon wavefields are used to probe the sub-dermal structure of the human body.

ABSTRACT

We address the problem of detecting buried mines or objects from multichannel sequentially collected ground penetrating radar (GPR) data for applications such as landmine and unexploded ordnance remediation, utility line mapping, and archaeology. Usually, the exact form of target signal is not known. We develop and analyze a low-complexity, decision-theoretic, sequential detection strategy to solve this problem. At each stop of the array, a windowed ANOVA test is designed to look for significant difference among the multichannel signals and suppress accumulated noise. A sequential estimator-detector then processes the ANOVA results to detect mines as array proceeds down track. Its performance in terms of mean time between false alarms and probability of detection is analyzed. Results from applying the method on real-world data are presented.

1. INTRODUCTION

The use of ground penetrating radar (GPR) arrays for detecting buried objects has received considerable attention in recent years in areas such as landmine and unexploded ordnance remediation, utility line mapping, and archaeology [9]. A typical GPR configuration for such applications is shown in Fig. 1. Here one array of transmitters and a second array of receiving elements are simultaneously moved down a linear track. At every stop of the system, each transmitter emits a short pulse of electromagnetic energy which interacts with the surrounding medium. Based on observations of scattered fields collected by the receivers the objective of the problem is to determine if an object is present in the field of view of the array.

Current processing methods for this problem fall into one of three categories. First, pattern matching methods [5]

employ techniques such as fuzzy set theory and neural networks. Such methods can be fast but also require extensive training to function well. Moreover, performance analysis is limited to Monte-Carlo simulations. Second, image-then-detect techniques [4] employ a beamforming or backpropagation approach to build an image of the subsurface which is then post-processed to detect objects. Such methods generally require the data from the full GPR scan to form an image and are thus not well suited to on-line computations in which information is processed sequentially as the array proceeds down track. More subtly, the attenuation associated with the propagation of the GPR signal typically results in useful signal only over receivers located closest to the firing transmitter. In many functioning systems in fact only a single receiver is employed per transmitter. Thus, methods based on beamforming which require array-based observations are not really appropriate for this problem. Finally, there has been some very interesting work done in the area of statistical processing methods [3] where one can examine quantities such as detection rates, false alarm probabilities, etc.; however the techniques in [3] for instance are based on highly complex electromagnetic models for the GPR sensor and are thus computationally intensive.

With this as background, here we view the GPR detection problem in a multichannel (one channel per transmit/receiver pair) blind signal detection framework and employ statistical methods to process the GPR returns. This approach allows us to exploit two generic properties of the signal transmission process. First, for any given stop of the array, the presence of the mine close to a transmitter-receiver (T/R) pair results in a jump in the mean value of the observed signal relative to that seen in other pairs. Thus, we develop a windowed ANOVA test [7] to detect this change. Second, physical principles dictate that as the array moves from one stop to the next, this jump will be detectable only for those positions of the array close to the object; that is, the jump will be transient [9]. This behavior is exploited in the synthesis of a sequential detector to process the output of the ANOVA test as the GPR system moves down the track.

Figure 1: Setup of GPR array.

The paper is organized as follows. Section 2 discusses physical model of a GPR system and corresponding mathematic model. In Section 3, we present a statistical algorithm to detect mines and analyze its performance in mean time between false alarms between false-alarms and probability of detection. Conclusion and direction of future work is given in Section 4.

2. MODEL

2.1. GPR Model

To start, we consider a simple model of the GPR returns [2]. In addition to sensor noise, there are two primary components in the GPR signal. One always sees a signal due to the specular reflection of the transmitted signal from the ground. While there are many ways of modeling this ground bounce signal [3], here we assume that it varies slowly as the array moves down the track so that it can be estimated and subtracted from the data.

If a subsurface scatterer is present, the receiver records signal from that source too. In Fig. 2 we plot the ground-bounce corrected data for single T/R pair obtained from field data as a function of down-track position of the sensor. That is, each column of this image is composed of the samples in the received waveform for a given stop of the array. As can be seen from this figure the target signal is transient in two ways. First, it appears only when the sensor system is in the vicinity (≈ 0.5 meter) of the mine. For most systems this implies that there are on the order of tens of stops of the array when the mine can be detected out of hundreds to thousands of array positions in a typical GPR survey. Second, when the system is positioned close to the object, the effects are only seen in a small number of samples of the received waveform.

Before proceeding, we make two observations regarding the signals in Fig. 2. First in general the precise form of the signal of interest is typically unknown due to variations caused by fluctuations in the electrical properties of the soil, unmodeled physical effects such as surface roughness, and variability in the signature caused by the unknown orientation of the target relative to the sensor. Indeed, Fig. 2 is typical of the variability seen in practice. Second for clar-

Figure 2: Signal generated from two objects buried at position 1.5m and 3.0m.

ity, we have displayed signals from two targets which are relatively easy to detect. Generally, even after removing the ground bounce other sources of noise and clutter can significantly reduce the detectability of the desired signal and increase number of false-alarms.

2.2. Mathematic Model

Based on this discussion, at down track position n of the array, we have the classic binary hypothesis model for the GPR signal returns

$$\begin{aligned} H_0 : \quad & \mathbf{x}_i(n) = \mathbf{w}_i(n) \\ H_1 : \quad & \mathbf{x}_i(n) = \mathbf{s}_i(n) + \mathbf{w}_i(n) \end{aligned} \quad (1)$$

for $i = 1, \dots, M$ where $\mathbf{x}_i(n)$ is the length K vector of time samples for the received signal from the i th T/R pair, $\mathbf{s}_i(n)$ represents the signal due to the target, and $\mathbf{w}_i(n)$ is measurement noise, assumed to be white and Gaussian with zero-mean and variance σ_i^2 . While the exact structure of \mathbf{s}_i is unknown, we see that the effects of this signal are to cause a jump in the mean of the \mathbf{x}_i for those n where the target is in the field of view of the GPR. Thus the statistical problem of interest in this work is to detect this transient signal based on data vectors from M sensors sequentially obtained as the system moves down track.

As detailed in the remainder of this paper, we approach this problem in two steps. First, we develop a method for detecting the presence of \mathbf{s}_i for a fixed location of the GPR. Second, we use this test in a sequential manner to process the returns as the system acquires new data.

At a given position of the array since we do not know of \mathbf{s}_i the statistical problem we pose is

$$\begin{aligned} H_0 : \quad & \boldsymbol{\mu}_i = \mathbf{0} \\ H_1 : \quad & \boldsymbol{\mu}_i \neq \mathbf{0}, \quad i = 1, \dots, M \end{aligned}$$

with $\boldsymbol{\mu}_i = E[\mathbf{x}_i]$. In many cases, analysis of variance (ANOVA) is used to solve this problem. Recently however, Fan [6], Fan and Lin [7], has noted that the performance of ANOVA suffers for problems when the signal of interest is

limited to a small number of samples in the overall observation vector as is the case for the GPR problem of interest here. Fan's original work was limited to problems in which the first m samples were used, with m found from the data. Here we consider a generalization of Fan's work to take into account the fact that for the GPR problem the transient object is significant over a window not generally starting with the first sample. Following the windowed ANOVA, we turn to a sequential probability ratio test (SPRT) to make on-line detection as new data is acquired.

3. ALGORITHM

3.1. Estimation and detection

Before describing windowed ANOVA, it is helpful to see why in some cases ANOVA loses its discrimination power. For example, assume we have one observation vector of size $K \times 1$, $\mathbf{x}_1 \sim N(\boldsymbol{\mu}, \sigma_1^2 \mathbf{I})$ and we wish to test $H_0 : \boldsymbol{\mu} = \mathbf{0}$ vs. $H_1 : \boldsymbol{\mu} = \boldsymbol{\mu}_1$. Standard ANOVA is to estimate $\boldsymbol{\mu}$ by \mathbf{x}_1 and use the testing procedure $X_1^2 = \|\mathbf{x}_1\|^2$. The approximate power of the standard ANOVA estimator-correlator test is

$$P_d(H_1|H_1) = Q\left(\gamma - \frac{\sum_{k=1}^K \mu_1^2(k)}{\sigma_1^2 \sqrt{2K}}\right) \quad (2)$$

where γ the test threshold and Q the complementary cumulative distribution function and strictly decreasing. If $\boldsymbol{\mu}_1$ is different from $\mathbf{0}$ for only a small number of k then as K goes large, $\sum_{k=1}^K \mu_1^2(k) \ll \sqrt{K}$. From (2), we then conclude that testing all dimensions of the data actually causes the test to lose power due to the accumulation of stochastic noise. This deterioration is reflected in the factor $1/\sqrt{2K}$.

Based on this observation, Fan *et al.* developed an adaptive windowed ANOVA test of the form described previously. Fig. 3 shows results from an ANOVA and a windowed ANOVA test for the signals in Fig. 2. The windowed ANOVA truncates observation vectors of length K to length L by two steps 1) discarding the first m_1 components which are consisted of ground-bounce only (the target reflected signal always comes after the ground-bounce) and 2) discarding the last m_2 elements which represent signal that has been attenuated too much to be meaningful for signal processing. Both the ANOVA and windowed ANOVA tests easily detect the stronger signal, at position 1.5m. For the weak signal at about position 3.0m, windowed ANOVA shows improved performance. Specifically, the peak in the windowed case is more clearly visible above the nominal "noise floor."

Generalizing windowed ANOVA to multiple observations, we build the test statistic as

$$X^2 = \sum_{i=1}^M \sigma_i^{-2} \|\mathbf{x}_i - \bar{\mathbf{x}}\|^2 \quad (3)$$

(a)

(b)

Figure 3: Test statistic, a) result of an ANOVA, using all dimensions of observations, b) result of a windowed ANOVA, using truncated observations.

with $\bar{\mathbf{x}} = \sum_{i=1}^M \sigma_i^{-2} \mathbf{x}_i / \sum_{i=1}^M \sigma_i^{-2}$. It is easily shown that

$$X^2 \sim \chi_{ML}^2(\delta^2) \quad (4)$$

where

$$\delta^2 = \sum_{i=1}^M \sigma_i^{-2} \|\boldsymbol{\mu}_i - \bar{\boldsymbol{\mu}}\|^2 \quad (5)$$

with $\bar{\boldsymbol{\mu}} = \sum_{i=1}^M \sigma_i^{-2} \boldsymbol{\mu}_i / \sum_{i=1}^M \sigma_i^{-2}$ and $\chi_{ML}^2(\delta^2)$ is the χ^2 distribution with ML degrees of freedom and non-centrality parameter δ^2 .

While windowed ANOVA detects difference among observations at one stop of the array, it does not capture the structure seen as the array moves down track. To improve detection performance, we employ a sequential detection scheme based on the processing of the windowed ANOVA statistic to look for the transient signal from one stop of the GPR array to the next. Hence, the two hypotheses are

$$\begin{aligned} H_0 : & \quad X^2(n) \sim \chi_{ML}^2(0) \\ H_1 : & \quad X^2(n) \sim \chi_{ML}^2(\delta^2(n)) \end{aligned} \quad (6)$$

for $n = 1, \dots, N$ where $\delta^2(n)$ is defined in (5). At stop n , the log likelihood ratio for this problem is

$$u(n) = \ln \frac{p_n(X^2(n))}{p_0(X^2(n))} \quad (7)$$

Figure 4: Sequential detection test statistic $U(n)$.

with $p_n(X^2(n))$ the $\chi_{ML}^2(\delta^2(n))$ PDF evaluated at $X^2(n)$ and $p_0(X^2(n))$ the $\chi_{ML}^2(0)$ PDF evaluated at $X^2(n)$. One difficulty with generating $u(n)$ is that $\delta^2(n)$ is typically not known *a priori* since the underlying μ_i are not assumed known. Here we construct a generalized log likelihood statistic. Typically, this is done by replacing $\delta^2(n)$ by its maximum likelihood estimate which for this problem is $X^2(n)$. After some experimentation in real data and computer simulation, we have found that performance can be improved by incorporating a one-step delay into the processing. Specifically, we estimate $\delta^2(n)$ as $X^2(n-1)$.

The full algorithm then is essentially a repeated sequential probability ratio test (SPRT) [1] and is summarized by the following steps,

- $U_1 = 0$.
- FOR $n = 2, \dots, N$
 - $\hat{\delta}^2(n) = X^2(n-1)$
 - Form $u(n)$ according to (7)
 - $U(n) = \max(0, U(n-1) + u(n))$.
 - IF $U(n) > \alpha$, declare object.
- ENDFOR

where α is a preset threshold. Fig. 4 shows the result of the algorithm applied on windowed ANOVA output of Fig. 3. Clearly, setting α below about 0.01 will allow both objects to be detected.

3.2. Performance

Performance of this algorithm is studied in terms of mean time between false alarms and probability of detection. Under H_0 , the test statistic changes as a Markov chain, with update $u(n)$ at each step. Under H_1 , the update $u(n)$ is changing, and therefore, the test statistics $U(n)$ can be described as an inhomogeneous Markov chain. One method of analyzing Markov chain is a matrix approach, which we will take in this paper. First, since ML is usually very large,

χ^2 distribution can be approximated by a Gaussian distribution. We then have

$$\begin{aligned} H_0 : X^2(n) &\sim N(ML, 2ML) \\ H_1 : X^2(n) &\sim N(ML + \delta^2(n), 2ML + 4\delta^2(n)). \end{aligned}$$

Second, suppose the update $u(n)$ and the interval $[-\alpha, \alpha]$ is uniformly quantized to $2k+1$ levels such that $v_0 = 0$, and $v_k = \alpha$. Let $\pi_{nl} = \Pr\{U_n = v_l | N > n\}$ for integer $l \in [0, k-1]$, and $\pi_n = [\pi_{n0}, \pi_{n1}, \dots, \pi_{n(k-1)}]^T$ denote the probabilities of $U_n = v_k$ on the condition that there is no alarm until after sample time n . We can write the transition matrix $C^{(n)}$ at step n as [8]

$$C^{(n)} = \begin{bmatrix} p_n^0 & p_n^{-1} & \dots & p_n^{-\gamma+1} \\ p_n(1) & p_n(0) & \dots & p_n(-\gamma+2) \\ p_n(2) & p_n(1) & \dots & p_n(-\gamma+3) \\ \vdots & \vdots & \ddots & \vdots \\ p_n(\gamma-1) & p_n(\gamma-2) & \dots & p_n(0) \end{bmatrix} \quad (8)$$

where

$$p_n(l) = \Pr(\log \frac{f_1^{(n-1)}(X^2(n))}{f_0(X^2(n))} = v_l) \quad (9)$$

and elements in first row of Eq. 8 are $p_n^i = \sum_{l=-\infty}^i p_n(l)$. Here $f_1^{(n-1)}(X^2(n))$ denotes the PDF of $X^2(n)$ under the alternative hypothesis H_1 and using $X^2(n-1)$ to estimate $\delta^2(n)$. Under H_1 , the transition matrix $C^{(n)}$ can be built using Eq. 8 for different n , since signal is time varying. The probability of detecting a signal of length n_d is then found from

$$P_d(n_d) = 1 - \mathbf{1}^T \prod_{n=1}^{n_d} C^{(n)} \pi_0 \quad (10)$$

where $\mathbf{1}$ is a column vector of all ones. And the mean time between false alarms \bar{T} is found to be [8]

$$\bar{T} = \mathbf{1}^T (\mathbf{I} - C^{(0)})^{-1} \mathbf{e}_1 \quad (11)$$

in which $C^{(0)}$ is the transition matrix under the signal-absent statistics and \mathbf{e}_1 is a column vector containing a one in position 1 and zeros elsewhere. With more levels of quantization, we obtain more accurate estimation of P_d and \bar{T} . Fig. 5 shows simulated results of the mean time between false alarms between false alarms under the null hypothesis H_0 . With a changing measurement noise level, probability of detection changes, as shown in Fig. 6.

Fig. 7 shows the probability of detection when the length of signal is changing. As expected, a signal of large transient length can be detected at a higher probability.

Figure 5: Mean time between false alarms with different threshold and number of quantization levels.

Figure 6: Probability of detection at different signal to noise ratio.

4. CONCLUDING REMARKS

In this paper, we have proposed a sequential, windowed ANOVA to process multichannel GPR returns. The method has a relatively low computational complexity and can be implemented in real-time. We have demonstrated the performance of this technique on a sample of field data. Future research will focus on adaptive sampling of received signal to take into consideration of roughness of ground-air interface; on-line localization will be integrated to allow detect-localize-detect and thus provides higher probability of detection.

Abstract Berenger's Perfectly Matched Layer (PML) Absorbing Boundary Condition (ABC) has greatly enhanced FDTD scattering analysis. In a discretized domain, however, performance is signal-dependent and large angle performance is poor due to a rapid reduction in layer decay rate. Increasing the conductivity to offset this reduction increases the discretization errors, especially at near-normal incidence angles. However, by carefully specifying the conductivity in each of the PML sub-layers, it is possible to balance the small and large angle performance. The signal-dependence of reflections may be described in terms of the number of spatial points per wavelength. This lends itself to an overall strategy for which to search for PML profiles that provide superior performance for waves incident on a PML at angles between 0° and 75° and signals that have at least 15 spatial points per wavelength sampling. A 1-dimensional projection method may be employed to allow an exhaustive search to become a viable alternative to optimization. Such a search provides profile pa-

rameters, that while not necessarily 'optimal', give excellent wide angle, wide band reflection performance.

I. INTRODUCTION

The Finite Difference Time Domain (FDTD) method for electromagnetic scattering problems is particularly useful because it is wideband, easily implemented and adaptable to a wide variety of problems. To keep FDTD simulations from becoming computationally expensive, edges of the computational domain must be kept as close to the scatterer as possible. To avoid reflections from the edges of the domain from scattered fields propagating in all directions, an Absorbing Boundary Condition (ABC) must absorb waves incident from all angles. Historically, ABCs have had only limited success in absorbing waves incident at all angles[2-5], but this recently changed with the introduction of the Berenger Perfectly Matched Layer (PML)[6].

The PML works perfectly in continuous analysis, absorbing waves incident at arbitrary angles with arbitrary attenuation. Unfortunately, in order to be used in computer simulations, the PML must be discretized. This discretization limits the conductivity increase for offsetting the reduction in decay rate as the angle of incidence increases and thus limits the overall performance of the PML. Although many efforts improve the PML[7-15], few of these deal with performance as a function of angle, choosing instead to concentrate on improving performance at normal incidence. Although large angle effects may be minor if waves incident on a PML at grazing angles reflect nearly normally incident on an adjacent PML, it has been shown [7] that there are several applications where this is not the case and that the performance at large incidence angles is important to the overall performance of the ABC. Consequently, the improvement of large angle performance of the PML is an important problem.

Discretization also prevents the PML from being signal-independent, as it is in the continuous case. Most investigators choose to describe this signal-dependence as a function

of frequency. Because FDTD involves spatial and temporal sampling, we suggest that it may be simpler to describe the signal-dependence in terms of spatial points per wavelength.

There has also been much effort to analyze numerical reflections in the PML in order to optimize[16-20] wave absorption. Obtaining a closed form expression for the reflection from a PML as a function of the PML parameters, however, is a difficult problem. This difficulty lies in the fact that numerical reflections are created each time a wave passes from one layer to another. These reflections, in turn, create more reflections as they encounter different layers. Keeping track of all reflections becomes increasingly difficult as the number of layers is increased. Furthermore, this type of analysis can only be performed for one frequency at a time, complicating any effort for optimization.

The approach being used for this current work is largely heuristic. We wish to understand the mechanisms that affect reflections from a PML in order to develop a strategy that will allow us to identify PML parameters that will provide enhanced performance over the widest range of angles and signals. With the aid of computational analysis tools, an automated search has been developed for PML parameters . Although the 'optimal' profile may depend on the specific application, the parameters determined in this analysis provide the best wideband, wide-angle performance reported in the standard literature.

II. REFLECTION DEPENDENCIES

The decay rate of the PML in continuous time and space is given as $\alpha = \sigma \eta_0 \cos \theta$ [9], where θ is the incidence angle, σ is the conductivity of the PML and η_0 is the impedance of free space. Note that the decay rate is proportional to $\cos \theta$. Since there is no reflection at the PML interface, σ may be chosen arbitrarily large in order to offset the loss of decay rate due to the $\cos \theta$ factor.

The geometry for the discrete PML is shown in Figure 1. The decay rate in the discretized PML also decreases with increasing angle. Unlike with the continuous case, the discretized σ_i in the i^{th} PML sub-layer may not be chosen arbitrarily large. In general,

since FDTD simulations calculate electric and magnetic fields on complementary overlapping lattices, they are sensitive to changes in the parameters of adjacent layers. Stated another way, at any air-PML or PML-PML interface, the discrete equations for the fields at the interface are dependent on unmatched conductivities.

As an example, assume that σ_i are constant over a PML half space. An incident wave encounters only one interface, that between free space and the PML. The difference equation for the field at the interface will be dependent on the conductivity of the free space ($\sigma=0.0$) and the conductivity of the PML ($\sigma=\text{constant}$). If σ is very small, the resulting reflection will also be very small. If σ is increased, the decay rate increases, but there will also be a larger reflection from the interface. If a gaussian pulse, $\text{Exp}[-c^2(t - t_0)^2/W^2]$, where t_0 is the time at which the pulse is at its maximum, excites the first row of an FDTD grid, Figure 2 shows the total reflection from a constant conductivity PML half space versus angle for values of σ equal 0.15, 0.3, and 0.45 S/m. For these simulations, the temporal increment $\Delta t = 10\text{pS}$, spatial increment $\Delta = 0.012\text{m}$ and $W = \frac{50}{3}\Delta = 0.2\text{m}$. It is apparent that the reflection increases with an increase in σ , and that as θ increases the discrete change in conductivity at the interface is moderated and the reflection decreases.

It should be noted that the time and space steps need not have physical units. Instead, the entire FDTD simulation including the PML may be entirely specified by the Courant number $R = c\Delta t/\Delta$ and the i^{th} layer decay rate $S_i = \sigma_i\Delta\eta_0$ and the performance of the PML may be parameterized in terms of two unitless parameters: $S = (S_1, S_2, \dots, S - N)$, λ/Δ and the angle of incidence, θ . Given these, Δ and the wave phase velocity all other physical quantities can be determined.

One way reflection from the PML is reduced is to vary the sub-layer conductivities from small values near the free space interface to larger values toward the final sub-layer. This profiling of PML conductivity improves absorption, providing an alternative to increasing the number of sub-layers, which is computationally expensive. Since incoming waves do not encounter larger values of σ until well within the layer, the reflections caused by these

larger jumps in conductivity are attenuated by the initial lossy layers both for forward and backward propagation. Yet even with the parabolic conductivity profile $\sigma_i = \sigma_f (i/N)^2$ [6], the total reflection from an 8-PML at 75° incidence is shown to be about -33dB , compared to the -100dB achieved at normal incidence. It is noted that as the angle of incidence is increased, the numerical experimental results more closely match the theoretical loss, which for the case of [6] at 75° , was -31dB . This can be explained by the fact that as the angle of incidence is increased, the projected spatial increment $\Delta \cos \theta$ decreases, which has the effect of decreasing the discretization error, and the jumps in conductivity variations at every layer interface are smaller, giving lower sub-layer reflections.

Since $\sigma^*/\mu_0 = \sigma/\epsilon$, where σ^* is the magnetic conductivity, σ/ϵ may be used in both Ampere's and Faraday's laws [13]. Discrete conductivity values σ_n can be assigned to every half sub-layer. Using the half-layer profile specification and assuming no discretization error, the two-way loss equation is:

$$L = e^{-2 \sum_{n=1}^{2N} \sigma_n \eta_0 \cos \theta \frac{\Delta}{2}} \quad (1)$$

with conductivity profile taking the form $\sigma_n = \sigma_f (n/2N)^p$, $n = 1, 2, \dots, 2N$. For this profile form, the decay rate S may be described by $S_f = \sigma_f \Delta$ and p . A conductivity profile with a power dependence is simple to implement and does not change as rapidly as a profile with an exponential dependence, which was found to not perform as well.

The three different time-domain signals shown in Figure 3 have different temporal increments (Sig.1 $\Delta t = 2ps$, Sig.2 $\Delta t = 1.8ps$, Sig.3 $\Delta t = 1.7ps$), as well as the different waveforms which account for the different frequency contents. These signals have been used as the excitation for a 1-dimensional FDTD simulation to test various PMLs with perfectly conducting terminations. In each case, the Fourier transform of the reflected field divided by the Fourier transform of the incident field has been plotted versus the inverse of the discrete frequency, $2\pi/\omega\Delta t$, times the Courant number, R , which is also the number of spatial points per wavelength, λ/Δ . The use of non-physical units to describe

PML reflection has also been used in [22]. The incident waveform was obtained by using a much larger FDTD simulation where the wave passes over the receiver location just outside the PML and the simulation is stopped before reflection can occur. Results for the 1-dimensional FDTD simulations at normal incidence in Figure 4 show all three signals practically overlapping for all three PML layer configurations of $N = 8, 10, 12$. The layer size and normalized conductivity profile is indicated for each set of graphs. Note that since the curves coincide for each PML configuration, PML reflections are independent of R and of the waveform, but dependent primarily on the relationship between the two (i.e λ/Δ).

To further investigate the PML reflection dependencies, we consider the same three signals, but in this case maintain the temporal increment and conductivity profile, but use three different spatial increments and hence different Courant numbers and different values of the decay rate S . Here we test the 8-layer PML only, the results are in Figure 5. Note that the magnitudes of the reflection coefficients for the different signals are very different.

These figures clearly indicate that it is not the physical quantities ω and σ that determine the reflection from the PML, but rather the non-physical quantities S and λ/Δ . This intuitive result follows since the PML works 'perfectly' in the continuous domain specified by physical parameters, while reflections that arise from the discretized PML depends on discretization parameters.

III. EXHAUSTIVE SEARCH VS. OPTIMIZATION

One obvious method for improving PML performance is to optimize the PML parameters S_f and p over all angles and signals. To do this would require an analytic expression for reflections from the PML as a function of the size of the PML, incident angle, incident signal, S_f and p . Such analytic expressions which have been numerically verified for small N PMLs appear in the literature [18,22]. For an 8-layer PML, analytic expressions in the literature have not been found to accurately predict numerical reflections for all angles and

incident waveforms.

Even assuming confidence with an analytic expression of the reflection coefficient, optimization of the PML over all profiles, signals and angles is a non-trivial problem. By relaxing the 'optimality' requirement, we may utilize an exhaustive search to identify profiles that will provide superior performance over a wide range of signals and angles.

IV. EXHAUSTIVE SEARCH

The basic idea behind the exhaustive search is simple: FDTD simulations are run for each PML profile under consideration. The search continues until suitable profile parameters have been identified. Because we must account for both the angle-dependence and signal-dependence, however, steps must be taken to make the search viable and manageable.

Having described the PML signal-dependence, we now consider angle-dependence. Similar to an optimization problem, we must create a criterion on which to judge the results. Furthermore, recall that the decay rate, α in the PML is given as $\alpha = \sigma \eta_0 \cos \theta$. Therefore, regardless of the profile, we can expect significant reflection from a PML with a perfectly conducting termination at very large angles. It is therefore appropriate to introduce a weighting function. To improve large angle performance without sacrificing near-normal performance, we have chosen the simple 'minimax' criteria with a weighting function:

$$C(S_f, p, \lambda/\Delta) = \max_{\theta} \{ |\Gamma(\theta, \sigma_f, p, \lambda/\Delta) W(\theta)| \} \quad (2)$$

where $W(\theta)$ is a weighting function and $\Gamma(\theta, \sigma_f, p, \lambda/\Delta)$ is the reflection from the PML. Note that C is not a function of θ . We seek the values of S_f and p that minimize C . This function is well-suited to the wide-angle minimum reflection because it does not penalize for a realization of $\Gamma(\theta)$ that has a large variation. The weighting function, $W(\theta)$ is equal to unity (0dB) up to and including 60° , at which point it drops off at $-12dB/5^\circ$ to a

minimum of -36dB at 75° . This drop off from 60° to 75° accounts for the reduction in performance predicted by Eq. (1). Incident angles larger than 75° are not considered.

To deal the the signal-dependence, we describe reflection as a function of spatial points per wavelength and break incident signals into three groups. These groups have, respectively, a minimum of 15, 20 and 30 spatial point per wavelength sampling for frequencies that have power densities within -6dB of the maximum power density. The results reported in this work are therefore worst case reflections for signals adhering to these groups.

V. ONE DIMENSIONAL PROJECTION METHOD

Running a 2-dimensional FDTD simulation for every S_f and p is time prohibitive. Furthermore, depending on the type of excitation used, analysis of the reflection at a single angle is quite complicated. Fortunately, it has been shown 2-dimensional uniform plane waves may be represented using 1-dimensional FDTD simulations[21]. Reflections from a PML may also be analyzed using 1-dimensional FDTD simulations. Basically a 1-dimensional “slice” of a 2-dimensional wave is taken in the direction normal to the PML under test. This 1-D wave moves with a velocity $c/\cos\theta$, where c is the velocity of the 2-D wave in the propagation direction perpendicular to the planar wavefront. The PML only attenuates in the direction normal to its interface, so there are no transverse variations in the PML, but since the normal variations are specified by the same FDTD formalism as the 2-D, the 1-D FDTD simulation efficiently demonstrates the complete reflection and transmission characteristics of the PML.

This can be shown analytically. It has been shown [13] that the time harmonic curl equations for TM waves inside a continuous PML may be written as:

$$-\frac{\partial E_z}{\partial y} = j\omega\mu_0 H_x \quad (3a)$$

$$\frac{\partial E_z}{\partial x} \left(\frac{1}{1 - j\sigma/\omega\epsilon_0} \right) = j\omega\mu_0 H_y \quad (3b)$$

$$\frac{\partial H_y}{\partial x} \left(\frac{1}{1 - j\sigma/\omega\epsilon_0} \right) - \frac{\partial H_x}{\partial y} = j\omega\epsilon_0 E_z \quad (3c)$$

The time-harmonic plane wave solution for Eq. (3) is of the form:

$$E_z = E_0 e^{-jk_x^{pml}x - jk_y y + j\omega t} \quad (4a)$$

where the time dependence $e^{j\omega t}$ will be suppressed in the following:

$$\mathbf{H} = \frac{E_z}{\eta_0} (\hat{x} \sin \theta - \hat{y} \cos \theta) \quad (4b)$$

with

$$\begin{aligned} k_x^{pml} &= k_x \left(1 - j \frac{\sigma}{\omega\epsilon_0} \right) \\ &= \left(\frac{\omega}{c} - j\sigma\eta_0 \right) \cos \theta \end{aligned} \quad (5)$$

Note that the velocity of the 1-D slice inside the PML is $c/\cos \theta$. So the 1-D solution should take the form:

$$E_{1Dpml} = \hat{z} E_z \quad (6a)$$

$$H_{1Dpml} = \hat{y} H_y \quad (6b)$$

at $y = 0$.

Because the solution in Eq. (6) does not satisfy Maxwell's curl equations, Ampere's Law must be modified. Taking the partial derivative of H_x and H_y from Eq. (4b) with respect to y and x respectively at $y = 0$, with $k_y = (\omega/c) \sin \theta$ gives:

$$\frac{\partial H_x}{\partial y} = -jk_0(\sin^2 \theta) \frac{E_o}{\eta_0} e^{-jk_x^{pml}x} \quad (7a)$$

$$\frac{\partial H_y}{\partial x} = jk_0(\cos^2 \theta)(1 - j\sigma/\omega\epsilon_0) \frac{E_o}{\eta_0} e^{-jk_x^{pml}x} \quad (7b)$$

These are equated as:

$$\frac{\partial H_x}{\partial y} = \frac{-(1 - \cos^2 \theta)}{\cos^2 \theta(1 - j\sigma/\omega\epsilon_0)} \frac{\partial H_y}{\partial x}$$

Thus, the left hand side of Eq. (3c) becomes:

$$\frac{1}{\cos^2 \theta (1 - j\sigma/\omega\epsilon_0)} \frac{\partial H_y}{\partial x}$$

Now Eqs. (3) for the 1-D curl equations in the time domain becomes:

$$\frac{\partial E_{z1Dpml}}{\partial x} = \mu_0 \frac{\partial H_{y1Dpml}}{\partial t} + \frac{\sigma\mu_0}{\epsilon_0} H_{y1Dpml} \quad (8a)$$

$$\frac{1}{\cos^2 \theta} \frac{\partial H_{y1Dpml}}{\partial x} = \epsilon_0 \frac{\partial E_{z1Dpml}}{\partial t} + \sigma E_{z1Dpml} \quad (8b)$$

Eq. (8) should be recognized as the lossy Faraday and Ampere Laws with an impedance η^{pml} matched to that of free space: $\sqrt{\mu_0/\epsilon_0} = E_z/H_y$.

It can be shown that there are 1-dimensional equivalents for TE waves inside the PML as well. The derivation proceeds along similar lines.

To verify the proceeding derivation, we have run 2-dimensional FDTD simulations and compared them with the 1-dimensional equivalents. The results are found in Figure 6. In Figure 6, a TM plane wave incident at 30° is partially absorbed by an 8-layer PML at the back wall. The incident wave is propagating toward the left, rear corner. Figure 6b shows the reflected field. Note that the incident and reflected fields obeys Snells's law and that the reflected field is several orders of magnitude smaller than the incident field. Figure 6c shows a cross-section of the reflected field from the 2-dimensional grid taken at 50Δ from the right hand side as well as the reflected field from 1-dimensional simulation. The time stamp of the plots of Figure 6c are 150 timesteps from those of 6b. Note the similarities in the pulse shape and amplitude. The 2-dimensional plane wave was created by using 1-dimensional FDTD simulations on the left and right hand sides of the grid as described in [21]. The absence of additional reflection artifacts along the left and right sides indicate that the existing reflected field is generated from the PML only.

The 1-dimensional method comprises a simple and efficient means to test PML reflections. The attenuation is in one direction, the direction normal to the boundary. A careful

dispersion analysis shows that the error from representing a 2-dimensional wave with a 1-dimensional slice is comparable to the error involved in numerical dispersion which is inherent to 2-dimensional FDTD simulations. In two dimensions, Maxwell's curl equations for the PML require either a supplemental equation, as used in [13], or split-field equations, as used by [6].

Armed with this powerful tool, the search for S_f and p is greatly simplified and hence can be automated. A search program may iterate through different values of θ , S_f and p . Furthermore, since reflections can be described in terms of spatial points per wavelength, we may use a single wide-band incident wave as a test signal and be able to account for the signal-dependence of the PML as described in the previous sections.

VI. RESULTS

Using the techniques described in the previous sections, several automated searches were performed to identify the PML profile parameters S_f and p that will yield superior performance.

For each profile tested, a 1-dimensional FDTD simulation was run for every angle between and including 0° and 75° at 5° increments. In each case a wide-band test signal was the incident wave. The reflection coefficient is calculated by:

$$|\Gamma(\lambda/\Delta)| = 20 \log \max \left\{ \left| \frac{fft(E^s)}{fft(E^i)} \right| W(\theta) \right\}$$

where $\Gamma(\lambda/\Delta)$ is the reflection, E^s is the scattered field and E^i is the incident field.

Our experiments indicate that $\Gamma(\lambda/\Delta)$ becomes non-increasing after a certain value of points per wavelength, usual between 100 and 150. Therefore, once $\Gamma(\lambda/\Delta)$ has been calculated for a given profile and angle, the maximum between 15, 20, 30 and 200 points per wavelength respectively are recorded. Then these maxima are multiplied by the weighting function as necessary to yield the overall maximum for a given profile. The parameters that yield the smallest overall maximums are found in Table 1 through Table 4.

As the results reported in the tables are 'worst case' for the discrete frequency with the greatest reflection, depending on the incident time domain signal, results may be significantly better than those reported in the tables. For example, a gaussian pulse with a $10\Delta t$ time constant has been used as the incident signal to test plane waves incident on the PML at various angles for some of the profiles found in Tables 1 and 2. This is the same test signal used in [6]. The reflections coefficient as calculated by

$$|\Gamma| = 20 \log \max_{\theta} \left| \frac{E^s}{\max_t E^i} \right|$$

have been plotted versus angle in Figure 7 for the 8-layer PML with conductivity profile parameters $S_f = 0.016$ and $p = 3.74$. The results reported by Berenger [6] have also been plotted. Note that there is more than an order of magnitude improvement at both 45° and 75° . Using the same test signal, the reflection coefficient for a 10-layer PML with conductivity profile parameters $S_f = 0.025$ and $p = 3.91$ has also been plotted on Figure 7. Using an additional two layers, we may further decrease $\Gamma(\theta)$ by 2 orders of magnitude at 75° .

The improved performance shown by the 10-layer PML at large angles suggests that the weighting function may not be needed for larger PMLs. To explore this idea, several additional searches were performed without including the weighting function, the results for these searches are found in Tables 5 through 7. Although the results for searches that do not employ the weighting function are not quite as good overall, these profiles provide excellent performance across the entire range of 0° to 75° .

VII. CONCLUSIONS

We have explored the mechanisms that govern reflection from PML absorbing boundaries. In so doing, we have presented a simple means of accounting for the signal-dependence of PML reflections. Furthermore, we have shown that it is the 'discrete'

parameters points per wavelength λ/Δ and loss per PML sublayer S which govern this signal-dependence and not the 'physical' parameters ω and σ .

We have presented a fast and simple method to determine the reflection from a PML due to uniform plane wave at arbitrary angle. This method does not require the use of an anisotropic media or a split-field formulation. Plane wave decomposition may be used to gain insight into the overall reflection from arbitrary waves.

Employing these methods, we have conducted searches for conductivity profiles that provide improved performance. Assuming adequate sampling, profile parameters have been provided which will insure exceptional performance over a wide variety of scattering problems. This approach removes the burden of seeking adequate ABC absorption from the FDTD user.

Despite the obvious utility of the method, caution must be exercise to ensure that extreme angles ($> 75^\circ$) are minimized. The method developed here also does not account for evanescent waves.

ABSTRACT

A novel handheld time-domain array GPR antipersonnel mine detection system prototype has been developed. Using an offset paraboloidal reflector antenna to collimate rays from an ultra-wideband feed, the transmitted microwave impulse is concentrated forward, in front of the antenna structure. The resulting wave is a non-uniform plane wave over the portion of ground being investigated, and is incident at 45 deg. to normal. As such, much of the ground reflected wave is directed further forward, away from the operator, the reflector, and the receiving antennas, thereby reducing clutter. However, the wave transmitted into the ground, which interacts with the target, tends to have significant backscatter returning toward the receiving antennas. These receiving antennas are configured in a 2 by 2 array to provide spatial focusing in both along and cross-track directions. This is accomplished by measuring and comparing the backscattered signals at each receiver in the narrow time window between the times when the ground reflected wave passes the receiver and before this wave re-reflects from the reflector components.

Two-dimensional FDTD simulation of this parabolic reflector transmitter indicates that it generates a beam with a non-uniform planar wavefront, which scatters from rough ground primarily in the forward direction. The wave transmitted into the ground is also planar, propagating at the angle of refraction, and scattering fairly isotropically from a small penetrable target.

This system has been built and tested at Lawrence Livermore National Laboratory, using a very narrow pulse shape. LLNL's Micro-Impulse Radar (MIR) and custom-built wideband antenna elements operate in the 1.5 to 5 GHz range. One particular advantage of using the MIR module is its low cost: an important feature for mine detectors used in developing countries. Preliminary measured data indicates that the surface clutter is indeed reduced relative to the target signal, and that small non-metallic anti-personnel mines can be reliably detected at burial depths as shallow as 1 inch in both dry.

Keywords: GPR, mine detection, focused array, reflector antenna.

1. INTRODUCTION

There is considerable interest in the detection of shallow buried objects, such as mines and buried pipes, many of which are non-metallic. The detection of non-metallic objects, such as anti-personnel mines is challenging, since the differences between the dielectric constant of the target and the surrounding soil is relatively low. Since this contrast is low, the target scattering is small, in particular compared to the scattering by the ground surface.

To address the detection of plastic antipersonnel mines, which is also challenging for conventional metal detector, a novel handheld time-domain array GPR system prototype has been developed. Designed at Northeastern University, this detector makes use of an offset paraboloidal reflector antenna and an array of wideband receiving elements to provide moderate forward-looking capability with reduced surface clutter.

This new GPR system reduces this ground clutter by illuminating the sample ground surface with a forward propagating, quasi-planar wave, and receiving the scattered signals with a two-dimensional multistatic array. Since the scattering by a small target is relatively isotropic, while scattering by the ground is primarily specular, a planar transmitted signal is well suited for shallow GPR detection. Plane wave illumination has another advantage beside clutter reduction compared to point source excitations: for a given target burial depth, the wave incident on a target from a plane wave source will always scatter the same way. For a point source, the incident wave on a given target will be illuminated from the side for one transmitter position and directly above for another. The constant exposure angle for a planar wave excitation makes processing the returned signals more straightforward.

We have used the finite-difference time-domain (FDTD)¹ method to electromagnetically model our novel GPR configuration. We implemented the 2-D FDTD code to simulate the generation of the non-uniform plane wave, the scattering by the modeled dispersive soil ground surface, the scattering by the target, and the retransmission back into the air, confirming the clutter minimizing characteristics of this mine detector. Computer simulation guides optimum size and offset section selection of the reflector, the choice of height of reflector off the ground, and the best positions of receiving elements.

A prototype system has been fabricated and tested at Lawrence Livermore National Labs (LLNL) using an excitation signal that is sufficiently short in time duration to resolve small targets and discriminate the ground surface from a shallow buried target. The multistatic array concept provides for additional clutter rejection and time-domain focusing². This focusing is accomplished by measuring, comparing, and summing the backscattered signals at each receiver in the narrow time window between the times when the residual ground reflected wave passes the receiver and before this wave re-reflects from the reflector components.

2. GROUND PENETRATING RADAR GEOMETRY

The radar system makes use of an inclined transmitted plane wave impulse excitation in conjunction with a multistatic array of receivers. It is an essential aspect of the radar design to send out a very short pulse, and accurately measure the returned signal in very small time increments. The radar system would not function with stepped frequency excitation.

2.1 Parabolic Reflector Transmitter

In order to generate a plane wave near the ground surface, the transmitting antenna must collimate outgoing rays in a beam that illuminates the sampled region of ground. Not only must this antenna generate a planar wavefront, but also its aperture must extend a distance comparable to the distance to the ground. In other words, the ground must be in the near field of the antenna.

A reflector whose surface is a section of a paraboloid of revolution collimates rays emanating from a feed at its focal point. As long as the section of the paraboloid is as deep and wide as its height above ground, the wave it generates will remain planar over the illuminated region of ground. Outside the illuminated spot on the ground, the transmitted wave is not planar, but since most of the wave power is concentrated within the beam, this diverging field is relatively unimportant.

The orientation of this quasi-planar transmitted wave must be carefully selected to balance the clutter reduction and safety advantages of forward-look with packaging disadvantages. For greater wave incidence angles, the forward edge of the reflector must either be higher or farther forward. And since greater height requires greater aperture size, both options demand increased reflector size. As a compromise, the incidence angle was chosen to be at 45 deg. to normal. To maintain close proximity of the reflector to the ground surface, an offset section of the parent paraboloid is chosen for the reflector antenna.

Figure 1 shows the geometry of the parabolic reflector and the way it directs rays from the transmitting feed to the ground. Diverging rays leaving the transmitter reflect from the paraboloidal surface, emerge as parallel rays, in such manner as to keep the path length from the feed to an inclined wavefront constant. The inclined wavefront is perpendicular to -- and propagates along -- the axis of revolution of the parent paraboloid, which includes the parabola focus and vertex. Also, the reflector produces a beam of microwave energy with an abrupt drop in power outside the ray tube bounded by the perimeter of the reflector (indicated with rays in Figure 1). The distance along the rays from reflector to ground S is equal to the projected reflector diameter D (distance between the furthest rays), so the rays representing the transmitted wave will be parallel, and the wave will be planar. The governing equation for the nearfield of the reflector is: $S \ll 2 D^2 / \lambda$, so when the reflector is positioned close to the ground, the radiated wave is in the nearfield, and concepts of antenna gain and radiation pattern are irrelevant.

Figure 1. Geometry of the offset parabolic reflector

Because the transmitted wave diverges very little from reflector to the ground, most of the power incident from the illuminating feed is transferred to the ground. Much of the ground reflected wave is directed further forward, away from the operator, the reflector, and the receiving antennas. In addition, the wave transmitted into the ground is incident on the target in the same manner for any antenna position: always as a plane wave with constant soil path length and incident angle $\theta_i = \sin^{-1}(1/\sqrt{2\epsilon_r})$. Since the scattering from an electrically small buried target is primarily isotropic, there will be a significant backscattered signal, propagating oppositely to the surface clutter signal, returning toward the receiving antennas.

An offset section of the paraboloid is selected to avoid blockage of rays by the feed structure. In contrast to offset reflectors used in communications applications, this offset section is particularly deep, extending from the vertex past the focal point by twice the focal length, giving an F/D ratio of the parent paraboloid of about 0.15. The best offset section extends from 45 deg. to about 115 deg. from the symmetry axis, which ensures that the front and rear edges are at the same height above ground. For a parabolic focal length of 20 cm, the projected aperture diameter of the reflector is about 47 cm, which nominally illuminates an elliptical spot of ground with axes 47 and 67 cm. For a reflector positioned 33.5 cm above the ground, the center of this elliptical region is immediately below the front edge of the reflector, and all of the collimated rays from the reflector would reflect from a flat ground just missing the front of the reflector.

2.2. Receiver Array

The receivers are positioned under the reflector, but behind the point on the ground at the center of the illuminated spot. The 4 receivers are arranged in a rectangular 2 by 2 array, with the forward pair separated by about 40 cm, and the backward pair by the same distance, 20 cm behind the forward pair. Since the receivers are displaced from the centerline, they do not appreciably block any of the wave from the reflector to the ground. Since the receivers are behind the point on the ground where the central ray strikes the ground, they will completely miss the strongest ground reflection signal. The entire structure is less than 70 cm deep and stands within 40 cm of the ground, clearly small enough to be operated as a handheld sensor.

2.3. Excitation Pulse

The LLNL Micro-Power Impulse Radar (MIR) was used as the transmitter source for the fabricated mine detection prototype system². This radar source generates an impulse with pulse width of about 300 ps and frequency range from about 1.5 to 5 GHz (see Figure 2). The duration of the main pulse peak is short enough to resolve about 1cm in dry sand and 5 mm in moist loam. However, this short pulse also enhances the electrical size of the roughness of uneven ground surface. Without the radar's clutter

Figure 2. Measured excitation pulse of MIR radiated by the reflector feed.

suppression advantage of forward specular reflection of the ground reflected wave, it would be very difficult to distinguish the target signal. Although it would be desirable to minimize the continued “ringing” of the pulse, the large relative amplitude of the main peak and the characteristic shape of the adjacent peaks makes the processing of returned signals to identify target scattering relatively straightforward.

3. FDTD MODELING

In order to confirm the concept that a plane wave impulse will scatter from rough ground primarily in the forward direction, while scattering from a small buried target is relatively isotropic, we computationally model the problem using the Finite Difference Time Domain method (FDTD). Real soils have dielectric characteristics that are frequency dependent, and as such require convolution of the permittivity and conductivity with electric field for modeling propagation and scattering in the time domain. Since convolution over all time is computationally prohibitive, other modeling methods must be used³⁻⁵. We avoid time domain convolution by modeling the frequency dependent conductivity as a rational function of the Z-transform variable⁶ $Z = \exp(j\omega \mathbf{D} t)$:

$$\mathbf{s} (Z) = \frac{b_0 + b_1 \cdot Z^{-1} + b_2 \cdot Z^{-2}}{1 + a_1 \cdot Z^{-1}} \quad (1)$$

and assume a constant average dielectric constant. The parameters in (1) are chosen to match the experimental data, such as Puerto Rican clay loam (PRCL)⁷ with density 1.4 g/cc and moisture 10%, with a time step $\mathbf{D} t = 20\text{ps}$ ⁸: $a_1 = -0.88$, $b_0 = 0.9162$, $b_1 = -1.6766$, $b_2 = 0.7611$, and $\mathbf{e}_{\text{Avg}} = 4.2$. The expression for conductivity in Equation (1) is equivalent to the ratio $J(Z)/E(Z)$. By multiplying through by the denominators, and using the fact that Z^{-1} corresponds to a unit time delay, a finite difference equation relating current to E-field in the time domain is obtained. This relation, along with $D(t) = \mathbf{e}_{\text{Avg}} E(t)$ models the dispersive nature of the soil in a manner that is easily implemented in FDTD. The perfectly matched layer (PML) absorbing boundary condition is used in the FDTD model to terminate the computational grid^{9,10}.

The transmitting antenna is modeled in two dimensions with a point source feed backed with absorber, and a staircase approximated perfectly conducting parabolic arc reflector. The absorber backing prevents any direct radiation toward the ground, which would scatter, then reflect from the parabola and contribute to the overall clutter. Both TE and TM polarizations were modeled, with special care taken for the TE computations to avoid electric field singularities at the ends of the reflector. To test the detectability of buried objects, two cases were run for each polarization: one with a target present and one without. We examined rectangular targets with dimension 5cm by 10cm buried 5cm below the nominal ground surface. Both metallic and non-metallic targets under rough ground with mean height variation of 3cm were considered.

Figure 3 presents three images for the TM simulation for the metallic mine target. By convention, for two-dimensional numerical calculations, the transverse plane is the plane of the calculation. For this TM calculation, the electric field is perpendicular to the plane of the paper. The first image shows the total scattered field, with reflection and diffraction from the reflector, scattering from the ground, and the scattering of the mine. The second shows the field distribution for the same ground, but without the buried mine. The planar wave generated by the parabola clearly scatters from the illuminated region of rough ground in primarily the specular direction, remaining roughly planar. The third image shows the difference between the first two, representing the field scattered just by the mine, and then rescattered from the air/soil interface. This mine-scattered signal appears to be circular, showing that the electrically small target scatters almost isotropically, with very little specular reflection from the top of the flat metallic target.

It is clear which features due solely to the mine are present in the first image. Those features due to scattering from the ground, shown in the second image, are also easily distinguished in the first image. Since these two sets of features are clearly separable in space for this particular time sample, it is demonstrated that the ground surface clutter is suppressed by the geometry of the radar system. Positioning the receivers behind the point where the central ray of the reflector intersects the ground ensures that the signals received will be primarily from the mine target and not from the ground surface.

Figure 4 is similar to Figure 3, with a non-metallic mine target. In this more challenging detection case, the dielectric contrast is quite low, so the target scattering is much smaller. In fact, the contrast between the TNT target ($\epsilon_{\text{Avg}}=2.9$, $\sigma = 0.0005$) and the soil is less than between the soil and the air. It is thus much more important with the non-metallic target that the ground surface clutter be reduced with good sensor design. Figure 4 shows that again the mine target signal is spatially separated and easily distinguishable from the clutter signal.

Figure 3. TM 2-D FDTD simulation of the LLNL MIR pulse reflected from the indicated 45 deg. inclined offset parabolic reflector and interacting with rough dispersive PRCL: a) Total field with rectangular metal mine target buried 5 cm, b) Ground scattered field with no target, c) Mine scattered field resulting from the difference between a) and b).

Figure 4. Same TM FDTD simulation as Figure 4, for non-metallic AP mine. Reflector height above ground is increased 25 cm to show backscattering details.

4. PROTOTYPE SYSTEM AND RESULTS

The Lawrence Livermore National Laboratory MIR source is well-suited for the mine detection problem, having the particular advantages of being small and extremely low cost, which are important features for mine detectors used in developing countries. This source was assembled with the custom-built metallic offset paraboloidal reflector. Figure 5 shows the full mine detector prototype; Figure 6 shows the device performing measurements at the test site at LLNL. In this test, a non-metallic antipersonnel mine simulant was buried in dry sand 1 in. below a very rough surface. This is a particularly challenging detection problem, because the dielectric constants of the plastic body TNT filled mine and the surrounding soil are very close. In addition, the random rough surface height variation is of the order of the height of the mine, and its burial depth. Thus, the anomaly detection is frustrated by low signal to clutter both in terms of size and contrast.

The result of processing the measured signals is shown in Figure 8, with bright areas signifying anomalies. To process the receiver signals, the direct signal from the transmitter to each receiver is removed, and the resulting signals are aligned in time to focus on suspected targets. Although there is still appreciable clutter from the rough ground, the target is still visible in the center of the image, two-thirds of the way up. The extent of the rough ground variation precludes clutter suppression using purely signal processing means. However, by ensuring that the ground-scattered signal specularly reflects away from the receivers, the target signal can be discriminated from the clutter.

5. CONCLUSIONS

A novel GPR mine detection system that reduces ground surface clutter has been developed and tested. The detector uses an offset parabolic reflector to generate a forward propagating plane wave to illuminate the ground and a 2-dimensional multistatic array to focus and enhance the received backscattered signal. Numerical simulations support several design assumptions:

- 1) The measured excitation gives good resolution and sufficient penetration in realistically modeled soil.
- 2) The offset parabolic reflector converts circular waves emanated by a point source feed into a non-uniform plane wave.
- 3) Choosing an offset parabolic section avoids blockage in generating a forward propagating plane wave.
- 4) A forward-looking planar transmitted wave takes advantage of specular ground reflection, spatially separating the target signal from the clutter signal.

- 5) Positioning receivers behind the central transmitted ray allows the monitoring of the backscattered mine signal while avoiding the ground clutter signal.
- 6) Even for a rough surface with a buried non-metallic mine, FDTD predicts distinct target and surface scattered signals.

Measured signals using the LLNL MIR radar for rough dry sand indicate that small non-metallic mine targets can be detected and discriminated from the cluttered background, even when shallow buried to a depth of 1 in. below a rough ground surface.

Accuracy Considerations in Using the PML ABC with FDFD Helmholtz Equation Computation

Carey M. Rappaport, Misha Kilmer and Eric Miller

Center for Electromagnetics Research, Northeastern University, Boston, MA

Abstract—A careful analysis of discretization error in various implementations of Berenger’s PML absorbing boundary condition for the FDFD method applied to the Helmholtz equation is presented. Analytic and numerical formulations indicate the clear superiority of specifying the material characteristics in terms of the coupled Ampere’s and Faraday’s laws first, and then combining the first order differential equations into a discrete Helmholtz-like difference equation.

Index terms—FDFD, PML, Absorbing Boundary Conditions

I. INTRODUCTION

The introduction of Berenger’s perfectly matched layer (PML) absorbing boundary condition (ABC) [1] has significantly increased the performance and popularity of the finite difference methods of electromagnetic field computation. The time domain version (FDTD) [2-4] has seen explosive acceptance of the PML lattice termination in the past three years, while its use in the frequency domain (FDFD) [5,6] as well as in finite element methods [7-9] are considerably less popular.

One reason why FDFD is avoided is the perception that it is computationally expensive, requiring solutions of thousands or millions of simultaneous equations. Another flaw with this method is its reliance on highly non-reflective ABCs in preventing reflection from any point on the grid perimeter. In the frequency domain, small imperfections in the ABC can greatly degrade the true field solution in the propagation domain. The first concern is overcome by combining the complementary sampled Faraday’s and Ampere’s Laws into the Helmholtz Equation (thus reducing the number of unknowns by 67% in two dimensional problems), and by using preconditioned iterative methods [10]. The latter issue is successfully addressed with the PML ABC, but only with careful considerations. In particular, when using the Helmholtz equation, it is no longer possible to assume that the PML layer conductivity profile is piecewise constant. It is the intention of this study to demonstrate the subtleties required in applying the FDFD PML procedure to the Helmholtz Equation while preventing significant numerical errors.

II. FDFD PML FORMULATION

The essential aspect of the PML is the additional loss factor $S(n)$ —which depends on the direction n normal to a boundary. This unitless quantity alters the wave number in the PML according to the relation:

$$\begin{aligned} k_{\text{PML}n} &= k^{\text{rel}}(n)k_{0n} \\ k^{\text{rel}}(n) &= 1 - jS(n) \end{aligned} \tag{1}$$

This work has been supported by The Army Research Office, Multidisciplinary University Research Initiative Grant No. DAAG55-97-0013

(where n is the distance from to the layer boundary, $k_{\text{PML}n}$ and k_{0n} are the normal components of the PML and propagation space wave numbers) which multiplies the differential element of the direction normal to the layer boundary [6]. This PML factor can be considered a complex anisotropic mapping of the normal coordinate, or a stretching of the coordinate system in the normal direction [11,12], and follows from Maxwell's equations with the assignment $S(n) = \sigma(n)/\omega\epsilon_0$, where $\sigma(n)$ is the spatially dependent PML conductivity. With this choice, using the inverse dependence on frequency ω , the time domain transforms have frequency independent exponential decay with distance into the PML. However, in most lossy layer ABCs, the conductivity $\sigma(n)$ is profiled from small values closest to the propagation space interface to a maximum value at the PML termination. Both power and geometric series profiling have been studied for optimal absorption of incident signal [13-15].

In the frequency domain, the equations for a two-dimensional transverse electric (relative to the longitudinal direction z into the paper) PML region terminating a lattice at $x = x_{max}$ (assume, without loss of generality that $x_{max} = 0$) have the form:

$$\frac{\partial H_z}{\partial y} = j\omega\epsilon_0 E_x \quad (2a)$$

$$-\frac{\partial H_z}{\partial x} \left(\frac{1}{1 - j\sigma_e(x)/\omega\epsilon_0} \right) = j\omega\epsilon_0 E_y \quad (2b)$$

$$\frac{\partial E_y}{\partial x} \left(\frac{1}{1 - j\sigma_m(x)/\omega\epsilon_0} \right) - \frac{\partial E_x}{\partial y} = -j\omega\mu_0 H_z \quad (2c)$$

For the continuous case, $\sigma_e(x) = \sigma_m(x)$. Since the PML conductivity changes with distance, so does the loss factor $S(x)$ and the normal wave number $k_{\text{PML}x}$, and therefore the propagation behavior of the wave in the PML will not have a simple linear phase dependence. For continuously varying conductivity, the normal wave number for the boundary $x = x_{max}$ can be replaced by:

$$k_{\text{PML}x} \rightarrow \int_0^x k_0 k^{\text{rel}}(x) dx \quad (3)$$

where the conductivity $\sigma(x)$ is labeled differently for Ampere's and Faraday's laws. For the both the coupled first-order FDFD and FDTD formulations, in which the electric and magnetic fields are sampled on interlocking grid points [16], the values of PML conductivity can be thought of as piecewise constant, changing every one-half grid cell: $\sigma_m(x) = \sigma_i$, for $|x - i\Delta| < \Delta/4$ and $\sigma_e(x) = \sigma_{i+\frac{1}{2}}$, for $|x - (i + \frac{1}{2})\Delta| < \Delta/4$. Although a parabolic variation of conductivity with distance $\sigma_i = \sigma_f(i/N)^2$ for an N sublayer PML gives acceptable absorption [1], it has been determined empirically that an excellent choice of profile for wide-incidence angle matching to free space using an eight grid cell PML layer in both the time and frequency domains is [5,13]:

$$\sigma_i = \left(\frac{2i-1}{16} \right)^{3.7} \frac{0.02}{\Delta}, \quad i = 1, \dots, 8 \quad (4a)$$

$$\sigma_{i+\frac{1}{2}} = \left(\frac{2i}{16} \right)^{3.7} \frac{0.02}{\Delta}, \quad i = 0, \dots, 8 \quad (4b)$$

Using the Helmholtz equation with dependent variable H_z , instead of separate Ampere's and Faraday's laws with additional dependent variables E_x , E_y , leads to a three-fold reduction in the number of unknown discretized field values. Even using fast solvers for the sparse FDFD matrix equations, this reduction leads to great improvements in computation time. It is important to maintain the distance dependencies when combining the three first order TE equations (1) into the Helmholtz equation:

$$\frac{1}{k^{\text{rel}}(x)} \frac{\partial}{\partial x} \frac{1}{k^{\text{rel}}(x)} \frac{\partial H_z}{\partial x} + \frac{\partial^2 H_z}{\partial y^2} + k_0^2 H_z = 0 \quad (5)$$

for the continuous case. Note that if $\sigma(x)$ (and hence $k^{\text{rel}}(x)$) is treated as piecewise constant, an important first derivative term would be absent.

Discretizing Equation (5) for FDFD computation can be done in three ways:

(1.) Analytically expand the second partial derivative term to give:

$$-\left(\frac{1}{k_i^{\text{rel}}}\right)^3 \frac{\partial k^{\text{rel}}}{\partial x}|_{x=i\Delta} \left(\frac{H_{i+1,j} - H_{i-1,j}}{2\Delta}\right) + \left(\frac{1}{k_i^{\text{rel}}}\right)^2 \left(\frac{H_{i+1,j} - 2H_{i,j} + H_{i-1,j}}{\Delta^2}\right) + \left(\frac{H_{i,j+1} - 2H_{i,j} + H_{i,j-1}}{\Delta^2}\right) + k_0^2 H_{i,j} \approx 0 \quad (6)$$

where $H_{i,j} = H_z(i\Delta, j\Delta)$ and $k_i^{\text{rel}} = 1 - jS(i\Delta)$

(2.) Expand as in (1.), but use the discretized values of conductivity. The first term becomes:

$$-\frac{k_{i+1}^{\text{rel}} - k_{i-1}^{\text{rel}}}{2(k_i^{\text{rel}})^3 \Delta} \left(\frac{H_{i+1,j} - H_{i-1,j}}{2\Delta}\right) \quad (7)$$

(3.) Discretize the first-order equations (2) on one-half grid cell increments first, then combine them into the discrete Helmholtz equation:

$$\frac{1}{k_i^{\text{rel}} \Delta} \left(\frac{H_{i+1,j} - H_{i,j}}{k_{i+\frac{1}{2}}^{\text{rel}} \Delta} - \frac{H_{i,j} - H_{i-1,j}}{k_{i-\frac{1}{2}}^{\text{rel}} \Delta}\right) + \left(\frac{H_{i,j+1} - 2H_{i,j} + H_{i,j-1}}{\Delta^2}\right) + k_0^2 H_{i,j} \approx 0$$

which combines to give:

$$\left(\frac{H_{i+1,j} k_{i-\frac{1}{2}}^{\text{rel}} - H_{i,j} (k_{i+\frac{1}{2}}^{\text{rel}} + k_{i-\frac{1}{2}}^{\text{rel}}) + H_{i-1,j} k_{i+\frac{1}{2}}^{\text{rel}}}{k_i^{\text{rel}} k_{i+\frac{1}{2}}^{\text{rel}} k_{i-\frac{1}{2}}^{\text{rel}} \Delta^2}\right) + \left(\frac{H_{i,j+1} - 2H_{i,j} + H_{i,j-1}}{\Delta^2}\right) + k_0^2 H_{i,j} \approx 0 \quad (8)$$

Although each method is accurate to order $(k_0 \Delta)^2$ for functions which have Taylor series representations, the first method would appear to be the most exact, since it delays the discretization step to last, requiring the material parameters only at the central point of the three-point stencil. However, the third method incorporates three material parameters instead of just two (as with the other two methods), and will be shown to have the greatest accuracy.

III. ERROR ANALYSIS FOR FDFD DIFFERENCE EQUATIONS

To quantify the accuracy of the three discretization methods above, assume the continuous version of the 3.7 power conductivity profile given in (4) $S(x) = S_0 x^p$, where S_0 is constant with units m^{-p} . With this loss factor form, the corresponding exact plane wave solution to Equation (5) is readily computed using Equations (1) and (3):

$$H_z(x, y) = H_0 e^{-jk_{0x} x - jk_{0y} y - \frac{k_{0x} S_0}{1+p} x^{1+p}} \quad (9)$$

where the incident wave propagation vector is $\mathbf{k} = k_{0x} \hat{x} + k_{0y} \hat{y}$.

Applying this exact solution to each of the discretized Helmholtz equations (6-8) gives a measure of the discretization error. Care must be used in deriving the expansion of the exponential power functions for non-integer values of p . First, it must be understood that the small argument $\Delta \ll 1/k_0$ expansion relative to the central position (say x_i) in the stencil must take into account that the central position is itself an integer multiple of that small argument: $x_i = i\Delta$. Next, it is important to expand in terms which include both Δ and Δ^p . For *constant* S_0 , and non-integer p , the resulting lowest order error in approximating the differential Helmholtz equation (5) with the particular finite difference equation (6-8) (each divided by k_0^2 to normalize to distance) are respectively:

$$\frac{(k_{0x}^4 + k_{0y}^4)\Delta^2}{12k_0^2} + \frac{k_{0x}S_0\Delta^{p-1}}{k_0^2} \left(i^{p-1}p - \frac{(i-1)^{p+1} - 2i^{p+1} + (i+1)^{p+1}}{p+1} \right) \quad (10)$$

$$\frac{(k_{0x}^4 + k_{0y}^4)\Delta^2}{12k_0^2} + \frac{k_{0x}S_0\Delta^{p-1}}{k_0^2} \left(\frac{(i+1)^p - (i-1)^p}{2} - \frac{(i-1)^{p+1} - 2i^{p+1} + (i+1)^{p+1}}{p+1} \right) \quad (11)$$

$$\frac{(k_{0x}^4 + k_{0y}^4)\Delta^2}{12k_0^2} + \frac{k_{0x}S_0\Delta^{p-1}}{k_0^2} \left(\left(i + \frac{1}{2}\right)^p - \left(i - \frac{1}{2}\right)^p - \frac{(i-1)^{p+1} - 2i^{p+1} + (i+1)^{p+1}}{p+1} \right) \quad (12)$$

Note that in each of these expressions the leading term constitutes the standard FDFD error:

$$\frac{k_0^2\Delta^2(\sin^4\theta + \cos^4\theta)}{12} \quad (13)$$

for incidence angle θ and that the second terms are zero for $p = 1$ or 2 . For subsequent terms, the error is of higher order for $p > 3$. For non-integer p , no Taylor series exists for $H_z(x, y)$ as $x \rightarrow 0$, so the dependence on Δ can have order lower than $(k_0\Delta)^2$.

However, for predefined, frequency-independent loss of the form of Equation (4), $S_0 = \sigma_f/(N\Delta)^p\omega\epsilon_0 = \sigma_f\eta_0/k_0(N\Delta)^p$, a different expansion is needed. In this case, the dependence on Δ must be evaluated before the exponential function of Equation (9) is approximated. The first term of each error expression of Equations (10-12) remain the same, the lowest order dependence on Δ at the first layer ($n = 1$), for three cases now becomes:

$$\frac{U(\lambda/\Delta)}{2\pi} (f_1(p) + V f_2(p)) \quad (14)$$

$$f_1(p) = \begin{cases} p + \frac{2(1-2^p)}{1+p} & \text{method 1} \\ 2^{p-1} + \frac{2(1-2^p)}{1+p} & \text{method 2} \\ 2^{-p}(3^p - 1) + \frac{2(1-2^p)}{1+p} & \text{method 3} \end{cases}$$

$$f_2(p) = \begin{cases} p \left(1 - \frac{2^p}{(1+p)}\right) & \text{method 1} \\ 2^{p-1} \left(1 - \frac{2^p}{(1+p)}\right) & \text{method 2} \\ 2^{-p} \left(\frac{p(3^p-1)-2(1-2^p)^2}{1+p}\right) & \text{method 3} \end{cases}$$

$$U = \frac{\sigma_f\Delta\eta_0(\lambda/\Delta)}{2\pi N^p}$$

$$V = \frac{jU}{\cos\theta - jU}$$

with dependence only on the conductivity-grid product $\sigma_f\Delta$, the number of grid points per wavelength (λ/Δ) , the number of PML sublayers N , the and incidence angle θ . Note that the numerical error is not proportional to $\cos\theta$, indicating that although the numerical error is greatest for normal incidence, predicting the wide-angle absorption of a PML with given parameters is non-trivial.

Figure 1 shows the magnitude of the numerical error at normal incidence, for each of the three Equations (6-8), as a function of depth into the PML region, for the power parameter given in Equation (4), $p = 3.7$. The value of S_0 is chosen using $\sigma_f = .02/\Delta$, as in Equation (4) to provide an idealized two-way absorption of 223 dB, corresponding to an eight-layer loss of 2.67×10^{-6} . From Equation (9), $S_0 = -\ln(2.67 \times 10^{-6})(1+p)/(k_0(8\Delta)^{1+p})$. In this figure, $\Delta = \lambda/40$, implying $S_0 = 18511$ when $\lambda = 1$ m. The solid curve represents the first discretization method, Equation (6), the dotted curve represents Equation (7), and the dashed line corresponds to Equation (8). Clearly, the third method is superior. All curves indicate considerable error, over 100% at sublayer 5. These errors levels are due to difficulty in approximating the rapidly changing values of field within the PML layer. It is noted that if the conductivity variation is not included in the Helmholtz equation, the numerical errors are more than an order of magnitude greater than these presented in Figure 1.

For integer power $p \geq 2$ and constant S_0 , the numerical error for all three methods is $O(\Delta^2)$, but depends on the particular value of p . For the parabolic variation $p = 2$, the numerical error for each of the first two methods is given by:

$$\frac{(k_{0x}^4 + k_{0y}^4)\Delta^2}{12k_0^2} + j \frac{8k_{0x}^2 S_0 \Delta^2}{k_0^2} + \frac{2k_{0x} \Delta^3 S_0 i (k_{0x}^2 - j S_0)}{3k_0^2} \quad (15)$$

while for the third method, it is:

$$\frac{(k_{0x}^4 + k_{0y}^4)\Delta^2}{12k_0^2} + j \frac{5k_{0x}^2 S_0 \Delta^2}{k_0^2} + \frac{k_{0x} \Delta^3 S_0 i (4k_{0x}^2 - j S_0)}{6k_0^2} \quad (16)$$

Using the loss parameter for 120 dB two-way loss, PML(p, 8, 0.0001) as in [1], with the loss dependence specified in Equation (9): $S_0 = -\ln(10^{-3}) 3/(k_0(8\Delta)^3)$. When $\Delta = \lambda/40$ and $\lambda = 1$ m, $S_0 = 412$. In terms of conductivity,

$$\sigma_i = \sigma_f \left(\frac{2i-1}{16} \right)^2, \quad i = 1, \dots, 8 \quad (17a)$$

$$\sigma_{i+\frac{1}{2}} = \sigma_f \left(\frac{2i}{16} \right)^2, \quad i = 0, \dots, 8 \quad (17b)$$

with $\sigma_f = -3 \ln 10^{-6}/8\eta_0\Delta$

Figure 2 shows this numerical error dependence with sublayer number. The error for the third method is lowest for both the $p = 2$ and $p = 3.7$ cases.

IV. TWO DIMENSIONAL SIMULATION RESULTS FOR PML ABCS

The results of the previous section have been tested with a specific two dimensional FDFD scattering problem. The solution to the Helmholtz equation with a two dimensional point source:

$$(\nabla^2 + k_0^2)H_z = \delta(x - x_0, y - y_0) \quad (18)$$

(where δ is the 2D Dirac delta function) is given by the Hankel function $(j/4)H_0^{(2)}(k_0\sqrt{(x-x_0)^2 + (y-y_0)^2})$. To approximate the solution to Equation (18) a 3λ by 2λ space is discretized with an $121\Delta \times 81\Delta$ grid. The grid is surrounded by a PML layer of width 8Δ (that is, $N = 8$). The origin of the point source is $x_0 = -14\Delta, y_0 = -6\Delta$, where the origin (0,0) is assumed to be at row 41 and column 61 of the grid. The PML is terminated with a perfect magnetic conductor.

Discretization of Equation (18) together with either Equations (6) or (8) and lexicographical ordering of the unknowns leads to a system of linear equations $Ax = b$. The resulting matrix is sparse, complex, non-symmetric and non-hermitian. For this particular problem, A has dimension 13,192 but only 65,494 non-zero elements and is reasonably well conditioned; thus it was feasible to solve the system naively by Gaussian elimination. We note that a stable and fast approach effective at solving large systems of this type is given in [10].

Two separate experiments were performed, one in which we set the conductivity profile as in Equation (4) and then calculated solutions using Equations (6) and (8), respectively, and one in which we set the parabolic conductivity profiles as in Equation (17). All experiments were performed in Matlab in double precision floating point arithmetic. We used the Matlab command `besselh` to compute the analytic solution at our grid-points. For each of the two experiments, we compare our computed solutions with the analytic in terms of relative numerical error at each grid-point. That is, Figures 3 and 4 show values of $|H_{i,j} - H_0^{(2)}(i,j)|/|H_0^{(2)}(i,j)|$ corresponding to the two discretizations of the PML given in (6) and (8), respectively, where the profile is as given in Equation (4). Here, $H_0^{(2)}(i,j)$ is the value of the analytical solution at (x_i, y_j) and $H_{i,j}$ is our computed estimate of H_z at the same point. Figures 5 and 6 show the relative numerical errors when the profile is given by $p = 2$ and equations (6) and (8) are used for the PML, respectively.

Note that in both Figures 4 and 6 the symmetry of the numerical error patterns indicates almost no appreciable reflections from any of the grid edges. In addition, the pattern of numerical error is consistent with the standard angle dependent free-space FDFD sampling error, given by Equation (13); in other words, the PML is absorbing the wave as it should. However, the numerical error in Figures 3 and 5 is noticeably larger and the patterns seem to indicate reflection from the four side boundaries. These results are consistent with the asymptotic PML error results of the previous section.

V. CONCLUSIONS

The Perfectly Matched Layer can be efficiently implemented as the absorbing boundary condition for the Helmholtz equation FDFD method as long as the profiling of PML conductivities is incorporated into the computational stencil. A comparison of three methods of discretizing the Helmholtz equation with non-linearly increasing loss has shown that the numerical errors are smallest when the loss values are discretized first, at the first-order Maxwell's equations level, before combination into the Helmholtz equation. The error analysis is more difficult when the conductivity profile dependence has non-integer powers p of distance into the PML.

ABSTRACT

Northeastern University is heading one of three teams involved in five year, \$5,000,000 Multidisciplinary University Research Initiative (MURI) programs in demining, supported by the Army Research Office. The Northeastern effort involves a team of six other universities and small businesses and integrates electromagnetic, acoustic, and optical sensing modalities. We are designing sensors to measure many of the physical characteristics of the ground with and without mines, and developing carefully-tailored signal processing algorithms that specifically take the sensor and the physics into account.

Keywords: GPR, mine detection, focused array, reflector antenna.

INTRODUCTION

The best mine detectors, used in both US Army countermine operations and by humanitarian demining efforts that can afford them, are based on fifty-year-old technology comparable to metal detectors used by beach-combers. There is tremendous potential for improving the reliability of mine detection using state-of-the-art sensors, computer modeling, and signal processing, combined with the phenomenal recent advances in computer power. The overall goal of humanitarian demining is to use these tools to help people around the world clear hazardous land at a cost that even developing countries can afford.

The difficulty with finding buried mines is that there is no single type of “target”, nor surrounding background. In addition, the soil surrounding the mine often strongly absorbs electromagnetic radiation and may also have buried rocks, moisture pockets, tree roots, and bits of metal scrap (especially in a former battlefield). A rough soil surface may also randomly scatter much of the transmitted sensing signal and can be a significant source of detection noise. Conventional radar is relatively good at detecting metallic objects, both in the air and underground, but is much less effective at detecting nonmetallic targets, such as stealth aircraft or plastic mines. In addition, objects too close to the ground surface pose a problem in discrimination of the target from the ground surface itself. Thus, large metallic 30cm diameter anti-tank mines are relatively easy to find, but the 8cm anti-personnel mines with as little as half a gram total metal content, buried just 2 to 10cm under ground are quite difficult to detect. The need to find all sorts of targets, at depths varying from just below the surface to ten centimeters deep, in all terrain, from desert to rice paddy to rain forest, make mine detection a challenging problem.

Figure 1 illustrates four typical mine positions and approaches using conventional sensing modalities to detect them. Although there are newer and more exotic detection technologies being considered for mine detection, cost considerations preclude widespread acceptance for humanitarian demining. One promising novel detection modality which may become economically feasible is Nuclear Quadrupole Resonance sensing of the chemical nature of bulk explosives [1]

Figure 1.: Typical mine burial scenarios and appropriate detection modalities.

The sensing modalities alone are not enough to solve the mine detection problem. In addition, there must exist powerful physics-based and statistical signal processing algorithms to reconstruct the target features based on observed measurements. These algorithms in turn require computational models that allow for hypothesis testing, iterative or recursive estimation, and inverse scattering. Finally, since it is unlikely that a single detection modality will find every mine, it is important to combine the information from several sensing modalities with appropriate fusion techniques. The Northeastern University MURI strategic plan, showing the various overlapping efforts is shown in Figure 2.

The four main sensing modalities are ground penetrating radar (GPR), electromagnetic induction (EMI), infrared (IR), and acoustic detection. The processing approaches include parameter-based inverse scattering, recursive estimation, diffraction tomography, batch statistical detection, and

matched filtering. The stars with letter correspond to individual projects, abbreviated on the right. In the following sections, we will discuss a selection of these topics.

Figure 2: Northeastern University MURI project integration.

ELECTROMAGNETIC INDUCTION

Electromagnetic induction sensing of metallic objects is the standard subsurface detection modality. Metal detectors have been used since before World War II, and are quite effective in alarming on metal case mines and unexploded ordnance (UXO), such as shells and bombs (which are usually metallic). This technology can also sense the small metal firing pin almost always present in plastic and wooden mines [2]. However, when the EMI sensor sensitivity is set to detect such small metal targets, all sorts of man-made metallic and naturally occurring conductive clutter--such as nails, spent bullets, and bits of rust--is detected, and the false alarm rate becomes unacceptable. One approach to better discriminate targets from clutter and reduce the false alarm rate is to use wideband electromagnetic induction spectroscopy (EMIS) [3]. By examining the characteristics of the metal scattered signal from 30Hz to 24 kHz, and using a physical model of the target induced dipole moment, unique features of the mines in question can be distinguished [4].

GROUND PENETRATING RADAR

Ground penetrating radar is effective at identifying dielectric contrasts in the surrounding environment. If the dielectric contrast is large enough, the size of the mine target large enough, and the distance from the ground surface deep enough, it is possible to uniquely detect mines. However, distinguishing a nonmetallic mine from a dry or sandy soil background is quite challenging, because the dielectric constants of TNT and dry soil are practically the same. Also, for the case of antipersonnel mines, the target volume is small and it may only be buried a few centimeters below the surface. Removing the strong ground surface reflection clutter without overly suppressing the mine signal is a topic of active research [5].

Sophisticated electromagnetic modeling illustrates some of the problematic issues. Figure 3 shows two images created using the three-dimensional finite difference frequency domain (FDFD) method [6, 7]. Both images show the total E_x field at two planes above, on and below a random rough ground surface due to a Hertzian x-directed dipole above the ground. The left image shows the response when a rectangular nonmetallic mine target is buried 5cm down, while the right image results from a circular cylindrical mine with the same volume buried at the same place. Only by careful observation can the differences be observed. Clearly, sharp corners and smooth surfaces cannot be readily detected. In practice, direct comparison between the field configurations for known target cases is not possible. Even if the ground roughness could be measured and stored, computationally modeling the effects of the clutter cannot be accomplished in real time. The images of Figure 3 require approximately 50 hours of CPU time on a multiprocessor Compaq Alpha computer.

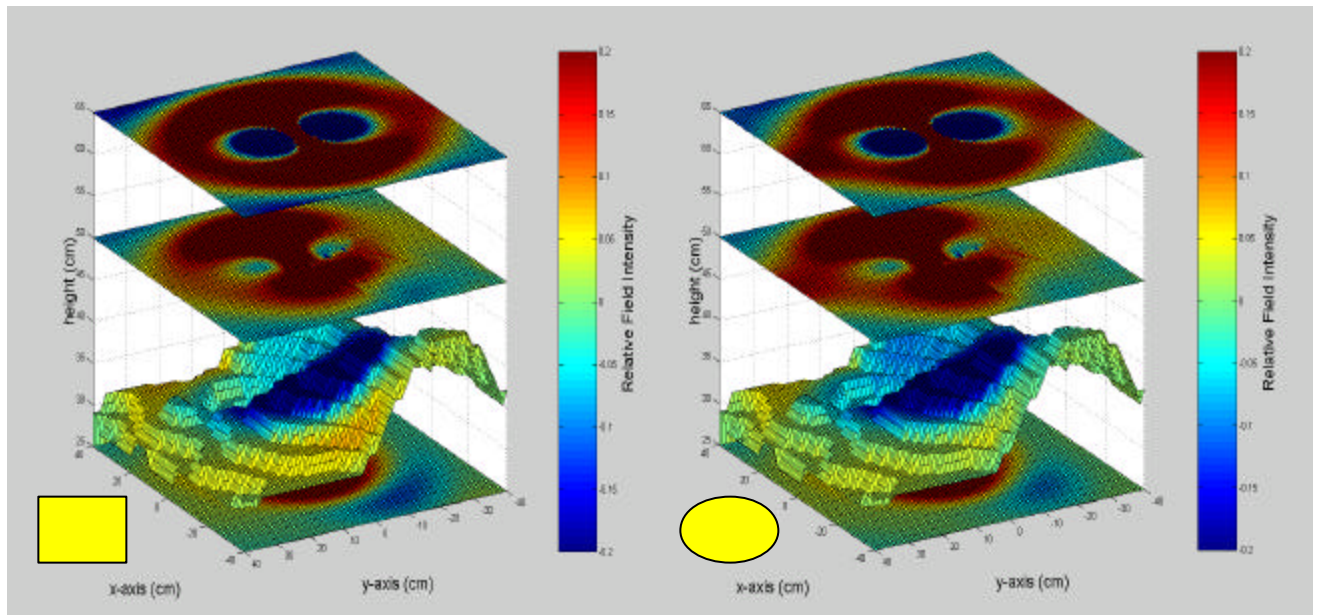

Figure 3: 3-D FDFD computational model of total E_x due to a dipole radiating at 960 MHz for a buried rectangular box target (left) and a circular cylindrical target (right) in clay loam soil with rough surface.

One of our major research projects is to improve the detection capability of ground penetrating radar by reducing clutter by simultaneously using multiple and receivers to focus waves on points under the ground surface. By “looking” at the mine from different angles at the same time, it is possible to emphasize the features of the mine, and minimize the clutter from the rough ground surface and uneven intervening soil. In addition, if the transmitted wave is planar and forward directed, the reflection from the ground surface tends to continue forward, away from the sensor. As such, it does not have as great an effect confusing the target signal. This effect has been confirmed both with computational models [8, 9], and in hardware, with an offset parabolic transmitting antenna [10]. Figure 4 depicts hardware fabricated by Lawrence Livermore National Labs. Test results for a nonmetallic mine buried in dry sand 1 inch under rough surface indicate an easily detectable anomaly with the size and approximate shape of the mine.

Figure 4: Offset parabolic reflector transmitter and multiple element receiver GPR handheld mine detector, with processed detection results for nonmetallic mine buried in rough sand

ACOUSTIC SENSING

Another exciting research area is the novel use of sound waves to detect acoustic echoes from buried mines. In deserts where the sandy soil is usually quite dry, non-metallic mines look electromagnetically very much like the background, and so are hard to pick out. To solve this problem, Northeastern University’s Demining team is using sound rather than radar or electromagnetic induction to find solid mine-like objects embedded in loose soil. The acoustic mismatch between granular soil and any metallic or non-metallic solid object is very high, giving a strong target-to-medium contrast.

One major problem with ground penetrating sonar is coupling through the ground surface. While medical ultrasound devices can be pressed firmly onto a patient's skin, direct ground contact in a minefield is not feasible. We have developed an alternative: using a laser beam to quickly heat the ground, causing rapid expansion, which in turn generates a sonic shock wave [11]. The scattered signals are detected either with a microphone placed very close to the ground, or interferometrically, using another laser beam to detect the ground motion.

This geometry, as well as sample detection results is shown in Figure 5. The mine simulant target is a bisected hockey puck, positioned slightly inclined to the ground surface. The surrounding material in this experiment was dry sand. A CO₂ TEA laser generated 150 mJ pulses several times a second, resulting in a string of acoustic pulses generated at the sand surface. A microphone was fixed relative to the laser, and the two were moved in a serpentine pattern relative to the ground. The measured signals were first filtered to remove as much of the ground surface reflection as possible, then the recorded signals were displayed as a function of position on the ground (bottom figure) [12]. The shape of the target is clearly distinguishable. It is also possible, by observing the arrival time of the target signal at the particular point, to determine the depth from the ground surface to the top of the target.

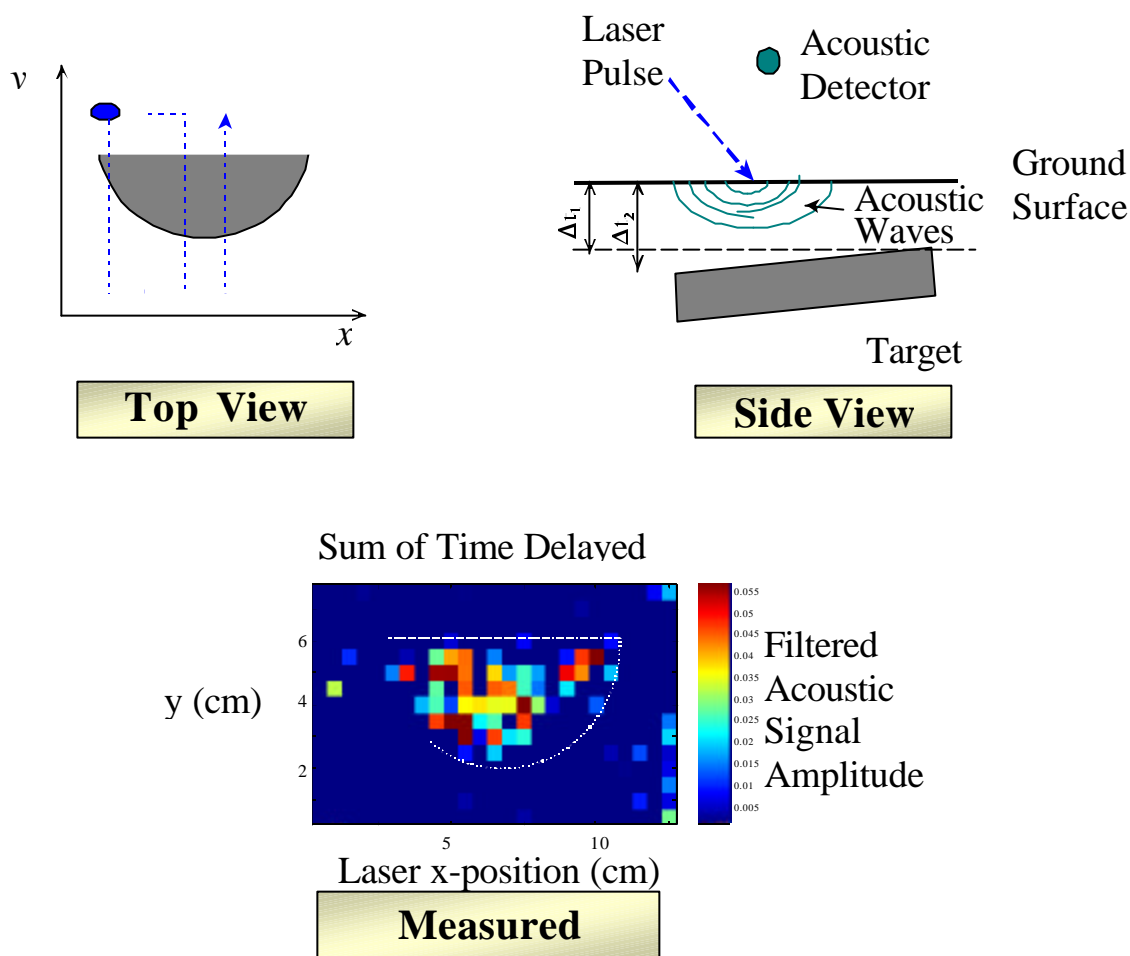

Figure 5: Laser induced acoustic sensing, geometry (top), and measured results (bottom).

INFRARED SENSING

Infrared detection is another sensing modality that has been used to find mines. Both polarimetric effects, which can distinguish exposed man-made objects [13], and thermal effects can be exploited. By measuring the subtle temperature changes from solar heating between soil with and without a mine, it is sometimes possible to find shallowly buried mines. Northeastern University's team has developed a novel means of using IR thermography by simulating the sun with microwave heating [14]. Our heater points down, toward the ground, deeply heating a small patch of soil. Meanwhile, we take IR pictures of the soil patch and look for anomalous heating patterns. Instead of being limited to sunrise and sunset, when the solar heating changes are most noticeable, our system can be used all day. Figure 6 shows this concept of heating the ground with microwaves. The right image indicates the temperature differences on the sand surface due to non-uniform heating of the soil above the targets. The shapes of the targets are clearly visible.

Figure 6: Microwave enhanced IR thermography concept (left) and measured results (right).

It is also possible to use multiple microwave frequencies for heating the ground. Since the surface heating pattern is relatively insensitive to frequency, while the heating at depth depends strongly on frequency, taking the difference from two heatings will better show the presence of buried anomalies [14].

CONCLUSIONS

In designing each of our sensors, our emphasis is to use as much of the available information as possible: use many different probing signals, with differing frequencies; use the widest possible view, with many inexpensive sensors coupled together; use the information gained from mine-free terrain and from confirmed terrain with mines to give improved detection confidence; use the fact that mines are stationary, while the detectors can move, and above all, keep the advanced technology simple in principle, so that it can detect mines in dirty, or frozen, or hard-to-traverse terrain.

ACOUSTIC SENSING

Another exciting research area is the novel use of sound waves to detect acoustic echoes from buried mines. In deserts where the sandy soil is usually quite dry, non-metallic mines look electromagnetically very much like the background, and so are hard to pick out. To solve this problem, Northeastern University’s Demining team is using sound rather than radar or electromagnetic induction to find solid mine-like objects embedded in loose soil. The acoustic mismatch between granular soil and any metallic or non-metallic solid object is very high, giving a strong target-to-medium contrast.

One major problem with ground penetrating sonar is coupling through the ground surface. While medical ultrasound devices can be pressed firmly onto a patient's skin, direct ground contact in a minefield is not feasible. We have developed an alternative: using a laser beam to quickly heat the ground, causing rapid expansion, which in turn generates a sonic shock wave [11]. The scattered signals are detected either with a microphone placed very close to the ground, or interferometrically, using another laser beam to detect the ground motion.

This geometry, as well as sample detection results is shown in Figure 5. The mine simulant target is a bisected hockey puck, positioned slightly inclined to the ground surface. The surrounding material in this experiment was dry sand. A CO₂ TEA laser generated 150 mJ pulses several times a second, resulting in a string of acoustic pulses generated at the sand surface. A microphone was fixed relative to the laser, and the two were moved in a serpentine pattern relative to the ground. The measured signals were first filtered to remove as much of the ground surface reflection as possible, then the recorded signals were displayed as a function of position on the ground (bottom figure) [12]. The shape of the target is clearly distinguishable. It is also possible, by observing the arrival time of the target signal at the particular point, to determine the depth from the ground surface to the top of the target.

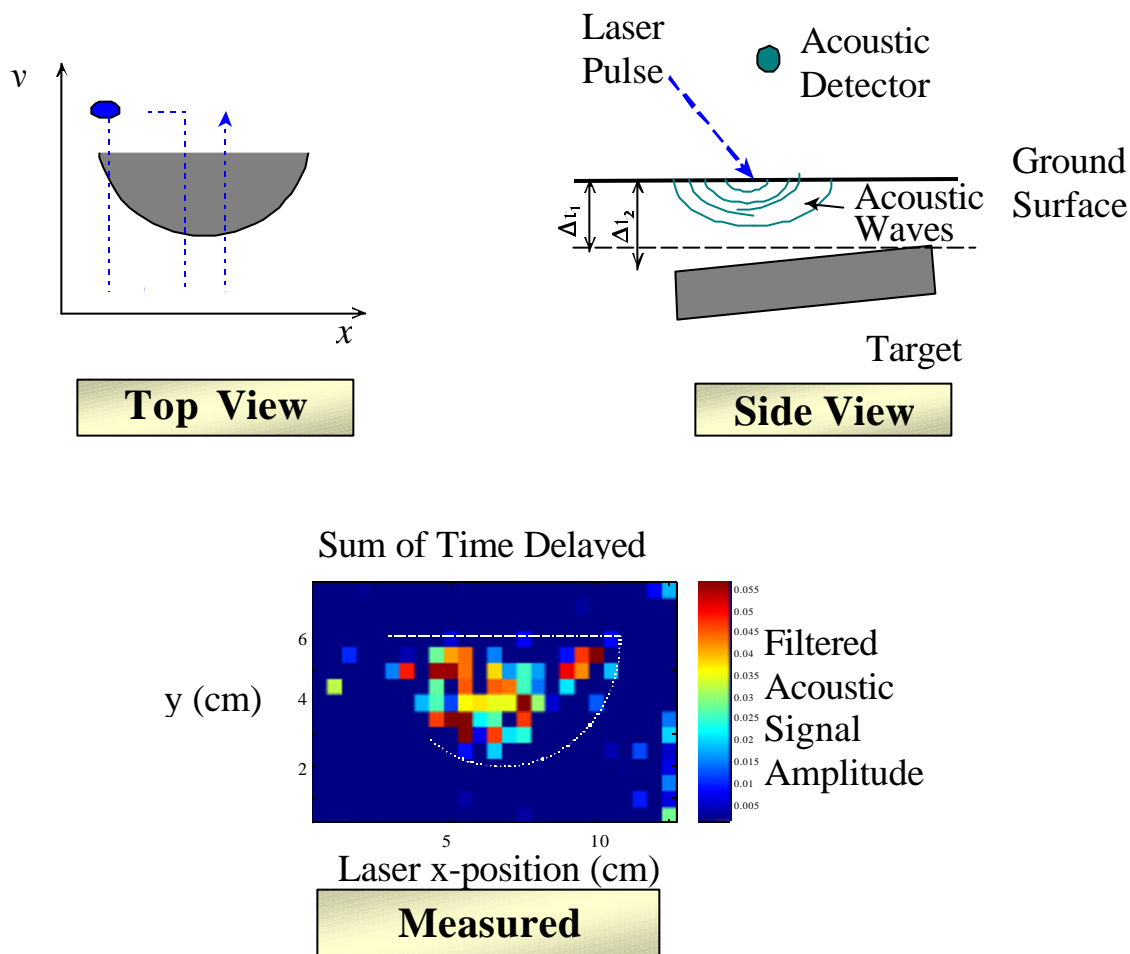

Figure 5: Laser induced acoustic sensing, geometry (top), and measured results (bottom).

INFRARED SENSING

Infrared detection is another sensing modality that has been used to find mines. Both polarimetric effects, which can distinguish exposed man-made objects [13], and thermal effects can be exploited. By measuring the subtle temperature changes from solar heating between soil with and without a mine, it is sometimes possible to find shallowly buried mines. Northeastern University's team has developed a novel means of using IR thermography by simulating the sun with microwave heating [14]. Our heater points down, toward the ground, deeply heating a small patch of soil. Meanwhile, we take IR pictures of the soil patch and look for anomalous heating patterns. Instead of being limited to sunrise and sunset, when the solar heating changes are most noticeable, our system can be used all day. Figure 6 shows this concept of heating the ground with microwaves. The right image indicates the temperature differences on the sand surface due to non-uniform heating of the soil above the targets. The shapes of the targets are clearly visible.

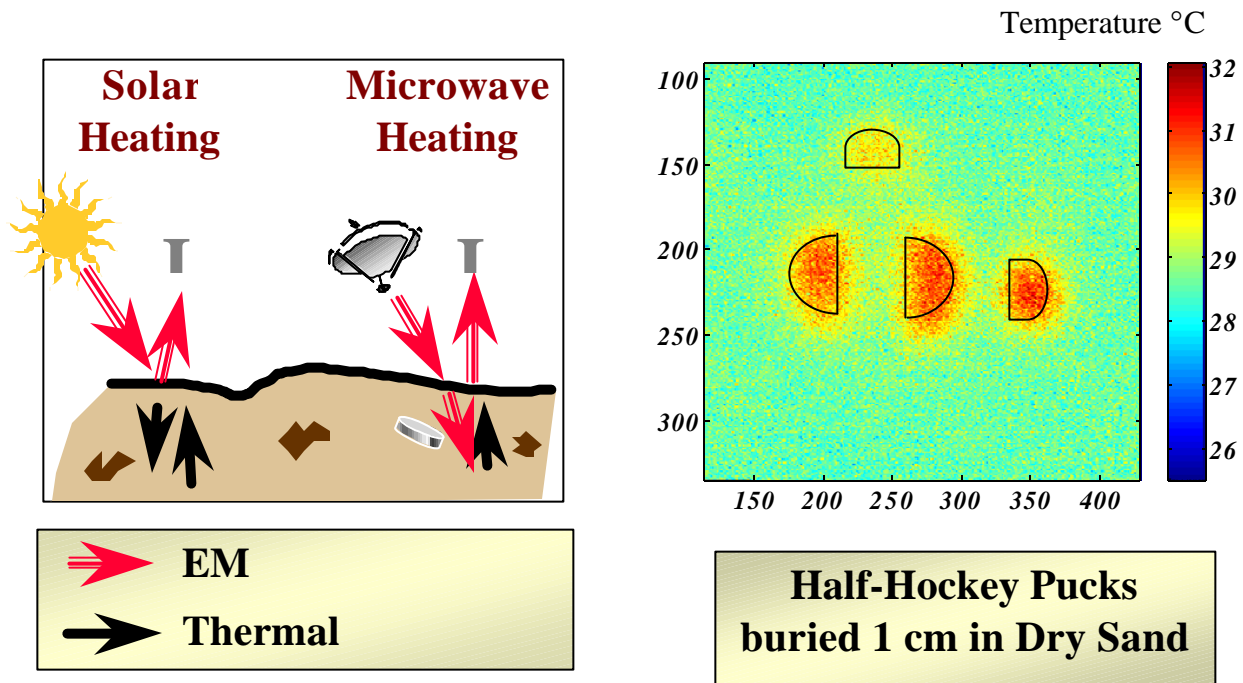

Figure 6: Microwave enhanced IR thermography concept (left) and measured results (right).

It is also possible to use multiple microwave frequencies for heating the ground. Since the surface heating pattern is relatively insensitive to frequency, while the heating at depth depends strongly on frequency, taking the difference from two heatings will better show the presence of buried anomalies [14].

CONCLUSIONS

In designing each of our sensors, our emphasis is to use as much of the available information as possible: use many different probing signals, with differing frequencies; use the widest possible view, with many inexpensive sensors coupled together; use the information gained from mine-free terrain and from confirmed terrain with mines to give improved detection confidence; use the fact that mines are stationary, while the detectors can move, and above all, keep the advanced technology simple in principle, so that it can detect mines in dirty, or frozen, or hard-to-traverse terrain.

Semi-analytic mode matching for detecting nonmetallic mines buried in realistic soils

Ann W. Morgenthaler and Carey M. Rappaport

Northeastern University, Boston, MA 02115

ABSTRACT

The ultra-wideband detection of plastic land mines buried in lossy, dielectric soils is simulated using a new semi-analytic mode matching (SAMM) algorithm. Here, we apply SAMM to the 3D canonical problem of finding the nonspecular reflection of an obliquely-incident plane wave on a lossy dielectric half-space containing a small, shallowly-buried dielectric sphere. However, SAMM can also be extended to smoothly-varying convex-shaped mines buried under modestly rough ground. In the SAMM algorithm, the frequency-dependent scattered fields are constructed from moderately low-order modal superpositions of spherical waves, each satisfying the Helmholtz equation in its respective material (air, ground, or mine). By least squares fitting, mode coefficients are found which optimally match all boundary conditions at designated points along the boundary surfaces. Spherical wave expansions are chosen at multiple coordinate centers so that small numbers of modes are needed to give convergent results.

The inverse discrete Fourier transform (IDFT) of a wideband GPR reflected signal yields a time domain signature dependent on mine and soil characteristics as well as the burial depth and radius of the mine in a particularly simple way: scattering times are dominated by analytically-computed Mie scattering from a spherical mine in an infinite soil background. Specifically, two or more characteristic time peaks are observed in SAMM simulations, suggesting that the ultra-wideband spectral radar response may yield particular advantages not exploited by currently-employed detection systems.

Keywords: GPR, mine detection, dielectric target imaging, modal analysis, ultra-wideband radar

1. INTRODUCTION

The challenging problem of detecting small, buried, nonmetallic objects (e.g., antipersonnel land mines) by GPR in lossy, dispersive, rough soil has been studied extensively,¹⁻³ and fully three-dimensional numerical methods (e.g., FDFD, FDTD,⁴ and moment method^{5,6}) tend to be computationally expensive and time-consuming ways to analyze real problems. Additionally, much of the radar literature analyzes far-field scattering of large, metallic objects in air,⁷⁻⁹ although antipersonnel land mine detection is usually performed in the near field; i.e., the radar transmitter and/or receiver are often held within a few wavelengths of the mine and/or ground surface. Therefore, many of the established far-field techniques are not applicable for detecting buried mines. Analytic simulations^{10,11} (e.g. integral equations, T-matrices) can often be difficult to implement for problems with half-space geometries. We therefore seek a hybrid method which is both physically-based and is applicable to a wide

range of geometries, with special emphasis on near-field scattering: the SAMM algorithm is one such approach.

In other papers^{12,13} we compare SAMM with FDFD simulations of a 2D buried cylinder under a ground plane, and find excellent agreement between the two methods, even when the ground surface is randomly rough, the ground material is modeled by a frequency-dependent complex dielectric constant, and the mine is not perfectly spherical.

Because SAMM is relatively fast and applies over a large frequency range, ultra-wideband frequency sweeps of the scattered fields can be simulated, enabling time-domain analysis of 3D buried mine scattering via the IDFT. Characteristic time peaks can be readily identified (even in fairly lossy ground media) which have a simple physical basis; a corresponding FDTD analysis would need to finesse the problem of dispersive media.¹⁴

2. SEMI-ANALYTIC MODE MATCHING (SAMM)

The geometry of the canonical buried mine problem is given in Fig. 1, where a sphere of complex dielectric ϵ_m and radius R is buried d meters below the surface of the ground; the perpendicular distance from the center of the mine to the surface is $\ell = R + d$. The ground has complex dielectric ϵ_g and extends infinitely far below the mine; the boundary between the ground and air is an infinite flat plane.

Since the mine is spherical, we describe the waves in each region by the electric and magnetic Hertz potentials¹⁵ Π^e and Π^m :

$$\mathbf{H} = \nabla \times (\mathbf{r}\Pi^e)/\eta; \quad \mathbf{E} = \nabla \times (\mathbf{r}\Pi^m) \quad (1)$$

which satisfy the scalar wave equation $(\nabla^2 + k^2)\Pi^{e,m} = 0$ where ∇^2 is the spherical Laplacian. The dispersion relation $k^2 = \omega^2\mu_0\epsilon$ must be obeyed in each of the three regions (air, ground, and mine). The Hertz potentials Π^e and Π^m therefore have the modal structure

$$\Pi^{e,m}(\mathbf{r},k) = \lim_{N_{\max} \rightarrow \infty} \sum_{n=1}^{N_{\max}} \lim_{M_{\max} \rightarrow n} \sum_{m=-\min(n,M_{\max})}^{\min(n,M_{\max})} C_{nm}^{e,m} f_n(kr) P_n^m(\cos\theta) e^{im\phi} \quad (2)$$

where the mode coefficients $C_{nm}^{e,m}$ have units of electric field and we assume a time-harmonic dependence $\exp(-i\omega t)$ with angular frequency ω throughout this paper. The spherical Bessel function $f_n(kr)$ has order n and possibly complex argument kr ; $P_n^m(\cos\theta)$ is the associated Legendre polynomial of order n and degree m .^{16,17} For the SAMM algorithm to succeed, it is crucial to expand the spherical modes about a proper choice of coordinate centers so that the fields converge with increasing mode integers n and m . Otherwise, the scattering fields cannot be constructed with a finite number of modes. In the discussion which follows, we shall consider only incident TE plane waves, as the TM case is easily found by duality.

We begin the SAMM algorithm by finding the reflected and transmitted plane waves that would exist were no mine buried below the ground. For oblique incidence, the usual textbook formulas result.¹⁸ The plane wave transmitted into the ground serves as the driving term for Mie scattering, which can be thought of as the first reflection from the mine before any rescattering from the air/ground interface has occurred. The transmitted plane wave must therefore be decomposed into spherical modes originating at the mine center with coefficients $C_{nm}^{e,m}$ given in Ref. [13]. Because the spherical mine has a boundary which falls along the contour $r = R$ in spherical coordinates, it is straightforward to match boundary conditions analytically on the spherical surface with the spherical modes, resulting in textbook Mie scattering fields.^{15,19} These Mie modes now drive further rescattering from both the air/ground interface and mine, described by spherical mode expansions about both the mine and its image in air; these rescattering modes, or r-modes, must be truncated to be useful in numerical simulations. That is, the radial mode index n is not allowed to exceed a specified N_{\max} while the angular mode index m is limited to the smaller of n and a specified M_{\max} . In the case of a normally-incident plane wave (which

Figure 1: Geometry of the buried land mine. A spherical mine with radius R and complex permittivity ϵ_m is buried a depth d below an infinite planar surface. Air (ϵ_0) extends infinitely far above and ground (ϵ_g) infinitely far below the ground plane. The coordinate systems C_0 , C , and C' are centered at the plane, mine and image mine, respectively, where the image mine is centered a distance $\ell = R + d$ above the plane.

can be generated by a dipole infinitely far above the ground plane), we can show that $M_{\max} = 1$, meaning that the field components have dipole-like $\sin \phi$ or $\cos \phi$ dependence.

In Fig. 2, we show the error caused by truncating the spherical mode expansion of a normally-incident plane wave as a function of N_{\max} for three values of $k_g R$ at the highest frequency in the simulation (8 GHz). Although it may be necessary to use 30-50 spherical modes to compose the plane wave accurately, the more computationally difficult rescattering can often be truncated after many fewer modes (10-20). In essence, rescattering is a local event, limited to a relatively small region of space, and constructed from modes centered near the observation point in the vicinity of the mine. In contrast, constructing an infinite plane wave from local spherical modes requires many more of them since the plane wave has infinite extent. Keeping large numbers of plane wave decomposition modes and their corresponding Mie scattering modes is simple computationally, since these mode coefficients are computed analytically from exact Mie solutions. Unlike the Mie modes, the r-modes are not decoupled because the planar boundary is not a natural contour in spherical coordinates: a single excitation coefficient leads to an infinite number of coupled spherical modes. Fortunately, *with appropriate choices for the scattering centers of these additional modes*, only a relatively few need be kept.

Figure 2: Error (dB) in decomposing a normally-incident TE plane wave in air [$\epsilon_g = \epsilon_0$], dry sand²⁰ [$\epsilon_g = 2.55(1+i0.01)\epsilon_0$], and Bosnian soil from the Alicia test site²¹ [$\epsilon_g = 8.66(1+i0.2)\epsilon_0$ at 8 GHz]. The discrepancy between the transmitted plane wave and its modal decomposition is measured on the surface of a 5-cm spherical mine. We observe that larger error results for a given truncation level N_{\max} in the soil with the larger dielectric constant.

Because each mode couples only to itself, the Mie coefficients can be computed analytically to any order in n and m . We expect that the plane wave plus the Mie scattering will account for much of the buried mine scattering. (For $\epsilon_g = \epsilon_i$, the Mie fields are the exact solution.) However, re-scattering from the planar boundary will lead to additional fields which we shall expand in spherical modes centered at both the mine ($z_0 = -\ell$) and the image of the mine ($z_0 = \ell$). Just as the simple problem of an antenna over a perfectly-conducting plane is solved by creating an image below that plane, we expect the image modes to model the infinite nature of the ground plane. Using the image scattering center for a modal expansion will allow convergence (and hence truncation) of the r-modes. We observe that modes will tend to converge only if all the centers from which scattered waves appear to originate are included; selection of the appropriate scattering centers can be more an art than a science, particularly in complex cases of irregularly shaped mines and rough surfaces. We may test the final solution in two ways: (1) by demonstrating convergence of the field to a stable value as more modes are chosen, and (2) by comparing field results to simulations of the identical geometry by established methods like FDFD or the moment method. We shall find that for the problem of a sphere buried under a flat surface, the actual scattering center plus image center is a reasonable way to implement SAMM. For a rough surface, these scattering centers will prove insufficient and additional ones will need to be chosen.

Once the scattering modes have been identified, we must ensure that the fields arising from the Mie and r-modes obey all boundary conditions (BCs) at the boundary surfaces. Were we satisfying BCs analytically, it would be sufficient to match the tangential components of \mathbf{E} and \mathbf{H} : four BCs would be needed at each boundary for a unique solution.¹⁵ Because we do not have a truly analytic solution (we are matching the field at discrete points), we shall enforce continuity of both tangential components of \mathbf{E} and \mathbf{H} as well as the normal components of \mathbf{D} and \mathbf{B} . We then use least squares analysis¹⁷ to find the mode coefficients that best fit the six BCs at each of N_{surface}

sampled surface points. We require all six (non-independent) BCs to be met at each point on each relevant surface, since minimizing the error in the four necessary BCs could lead to large errors in the remaining two, a common issue in least squares matrix inversion. There will be problems for which expansion in finite numbers of spherical modes will be quite difficult: targets which are not “fairly” spherical, mines with sharp protrusions, rough surfaces with steep slopes etc. are probably not amenable to modal expansion techniques. Although sharp metallic target corners, for which fields can approach infinity, are also poorly modelled with SAMM, the plastic antipersonnel mines for which SAMM simulations are successful present the greater detection challenge and are sufficient reason to utilize the new algorithm.

For an infinite planar surface, we shall not be able to allocate points in such a way as to completely cover the boundary. Placing a large fraction of the available points too far away from the region of the plane immediately over the mine results in inaccuracy near the mine, since the far points adjust the global behavior of unimportant regions of space and insufficient numbers of points are left to describe the near field. Conversely, placing points over too small a region of the plane results in modes which are highly degenerate; if the observation point is located above the plane (rather than on it), a wider planar region must also be covered. By comparing SAMM to standard simulations, we can get a sense of how best to allocate the surface points.

In summary, we implement SAMM by: (1) Choosing the appropriate scattering centers, about which modes will be expanded, (2) Creating a finite series of spherical modes with the appropriate values for wave numbers k and wave impedances η so that these modes automatically satisfy the Helmholtz equation in air, ground, and target material, (3) Allocating points on all boundaries and finding the mode coefficients which best fit—in the least squares sense—all boundary conditions at these points. We choose the spherical Bessel functions properly, so that radiation conditions and singularity issues are addressed: fields that fall within the origin of a modal coordinate system and fields which represent plane waves are specified by spherical Bessel functions of the first kind $j_n(kr)$, while scattering fields are described by outwardly-propagating spherical Hankel functions $h_n^{(1)}(kr)$, and finite regions which do not include the origin have two linearly independent field solutions.

3. APPLYING SAMM TO THE BURIED SPHERE PROBLEM

Referring to Fig. 3, we shall express the fields within each region of the problem as:

$$\Pi_{\text{air}}^{e,m} = \sum_{n=0}^{N_m} \sum_{m=-M_m}^{M_m} r_{nm}^{e,m} h_n^{(1)}(k_i r) P_n^m(\cos \theta) e^{im\phi} \quad (3)$$

$$\begin{aligned} \Pi_{\text{ground}}^{e,m} = & \sum_{n=0}^{N_{\max}} \sum_{m=-M_{\max}}^{M_{\max}} \left(C_{nm}^{e,m} j_n(k_g r) + A_{nm}^{e,m} h_n^{(1)}(k_g r) \right) P_n^m(\cos \theta) e^{im\phi} + \\ & \sum_{n=0}^{N_m} \sum_{m=-M_m}^{M_m} q_{nm}^{e,m} h_n^{(1)}(k_g r) P_n^m(\cos \theta) e^{im\phi} + \sum_{n=0}^{N_m} \sum_{m=-M_m}^{M_m} q_{nm}'^{e,m} h_n^{(1)}(k_g r') P_n^m(\cos \theta') e^{im\phi'} \end{aligned} \quad (4)$$

$$\Pi_{\text{mine}}^{e,m} = \sum_{n=0}^{N_{\max}} \sum_{m=-M_{\max}}^{M_{\max}} T_{nm}^{e,m} j_n(k_m r) P_n^m(\cos \theta) e^{im\phi} + \quad (5)$$

$$\sum_{n=0}^{N_m} \sum_{m=-M_m}^{M_m} t_{nm}^{e,m} j_n(k_m r) P_n^m(\cos \theta) e^{im\phi} + t_{nm}'^{e,m} h_n^{(1)}(k_m r') P_n^m(\cos \theta') e^{im\phi'} \quad (6)$$

The wave prefixed by the coefficient $C_{nm}^{e,m}$ is the transmitted plane wave, while the modes multiplied by $A_{nm}^{e,m}$ and $T_{nm}^{e,m}$ are the Mie coefficients of the first scattering from the mine; these Mie modes are truncated at N_{\max} and M_{\max} . The r-modes, truncated at $N_m \leq N_{\max}$ and $M_m \leq M_{\max}$, have coefficients $r_{nm}^{e,m}$, $q_{nm}^{e,m}$, $q_{nm}'^{e,m}$, $t_{nm}^{e,m}$, and $t_{nm}'^{e,m}$. Note that there is no part of the Hertz potential in air arising from the image scattering center; the image fields are valid only *below* the ground plane. In the case of a normal plane wave excitation, $M_m = M_{\max} = 1$

Figure 3: Schematic of plane waves, Mie modes, and spherical scattering modes (r-modes) in the SAMM algorithm. The incident plane wave (I) is reflected (R) and transmitted (T). This latter wave is decomposed into spherical modes, which lead to Mie scattering modes ($A^{e,m}$, $T^{e,m}$). These Mie modes reflect and refract at the ground plane, leading to r-modes ($r^{e,m}$, $q^{e,m}$, $q'^{e,m}$, $t^{e,m}$, and $t'^{e,m}$) valid in their respective domains as shown. The unprimed spherical modes originate at the center of the mine; the primed spherical modes originate at the image mine and the mode indices nm have been suppressed for clarity.

so each of the ten r-mode families will require $2N_n$ coefficients, leading to $20N_n$ unknown mode coefficients. For oblique incidence (or for rough surface scattering of any type of plane wave), $|m|$ is not limited to one and approximately $20N_m M_m$ coefficients will need to be fitted. Clearly, SAMM is tractable only if N_m and M_m are limited to relatively small values. Further analysis in this paper is limited to the case of normally-incident plane waves.

With the mode coefficients determined by inverting an overconstrained matrix equation having approximately $6N_{\text{surface}}$ equations and $20N_m$ unknowns so as to minimize the least squares error, the electric and magnetic fields can be reconstructed. Fig. 4 shows the transverse field component E_x plotted in both the y - z plane (at $x_0 = 0$), and x - y plane (at $z_0 = 0$). There is quite a striking difference between filling the ground with air, dry sand and Bosnian soil, with air-filled ground returning the strongest signal of the three. Determining mine signatures using air as the surrounding medium is clearly doomed to failure. Calculation of the r-modes for the single frequency in Fig. 4 took about 6 minutes in Matlab 5.3 on a Pentium desktop computer. The linear matrix has 4818×240 elements and is densely filled. A spherical Bessel function and a Legendre polynomial must be computed for each element, which is the major computational burden in the simulation. Although $N_m = 12$ in this simulation, $N_{\text{max}} = 25$ so additional special functions must be calculated for the Mie scattering which forms the right hand side of the overconstrained matrix equation. Using a compiled language would greatly increase computational speed.

Figure 4: Magnitude of scattered electric field $|E_x|$ at (a)–(c) $x_0 = 0$ (y - z slice) and (d)–(f) $z_0 = 0$ (x - y slice). A 3 GHz TE plane wave is normally incident on a half-space with ground having the electrical characteristics of (a),(d) air [$\epsilon_g = \epsilon_0$] (b),(e) dry sand²⁰ [$\epsilon_g = 2.55(1 + i0.01)\epsilon_0$], and (c),(f) Bosnian soil from the test site Alicia²¹ [$\epsilon_g = 8.82(1 + i0.13)\epsilon_0$ at 3 GHz]. In all cases, the mine is a 5-cm sphere filled with TNT²⁰ [$\epsilon_m = 2.9(1 + i0.001)\epsilon_0$] buried 5 cm below the ground surface. The mine and plane, where appropriate, are outlined in white on each plot. Because the gray scale is nonlinear to enable small amplitude features to be seen, note that the maximum field magnitudes are: (a) 4.5, (b) 0.80, (c) 0.80, (d) 0.33, (e) 0.018, and (f) 0.036 (normalized to the plane wave transmission coefficient).

4. MINE DETECTION USING SAMM

The electric field is plotted in Fig. 4 at a single frequency, but one of the powerful features of the SAMM algorithm is that it applies over a very wide frequency band. In Fig. 5, the electric field component E_x is plotted as a function of frequency at the observation point $x_0 = y_0 = z_0 = 0$, which is directly over the mine. Once again, the mine is a 5-cm radius TNT sphere buried 5 cm below the planar surface, the ground is either air, dry sand, or Bosnian soil, the excitation is a normally-incident TE plane wave, and the frequency sweep runs between 0.5 and 8 GHz in increments of 0.025 GHz. All components of electric and magnetic fields are matched at the planar and mine boundary surfaces at 401 and 258 points, respectively, and the planar data points are placed within a circle of radius 20 cm centered at the observation point. Because the plane wave is normally incident, the angular modes have only $\exp(\pm i\phi)$ dependence, so $M_{\max} = M_m = 1$. The radial mode cutoffs are $N_{\max} = 30$ (air), $N_{\max} = 40$ (sand), $N_{\max} = 50$ (Bosnian soil) and $N_m = 16$. The resulting frequency sweeps are windowed to eliminate the worst errors, caused by an insufficiently large area over which the planar points are placed at low frequencies, and too few r-modes (N_m too small) at high frequencies; the value of N_m is chosen to be a compromise between frequency range and computational speed. In these simulations, the plane surface points are placed along the intersections of evenly-spaced radial (ρ) and angular (ϕ) contours, the sphere surface points are evenly-spaced in the θ and ϕ directions, and all points are given equal weighting. The optimal locations and weightings for the surface points which minimize field error are still unknown.

Figure 5: Frequency and time domain IDFT of E_x calculated at the observation point $x_0 = y_0 = z_0 = 0$ for the case where the ground has the electrical characteristics of air (true Mie scattering). The upper left plot is the magnitude and phase (dashed line) of the scattered field E_x over the frequency range 0.5 to 8 GHz taken at intervals of 0.025 GHz. The plot immediately below is the r-mode scattering which is essentially zero because with no discontinuity between ε_i and ε_g , exact Mie scattering results. The bottom left plot shows the least squares error (lower curve) in the SAMM simulation and also the maximum error (upper curve) of any one point along the planar or sphere surface. The IDFT of the total scattered field (Mie plus r-mode) is given on the right. Both characteristic times T_0 and T_1 ($T_0 < T_1$) are clearly observed, as well as additional characteristic times separated by $\Delta t = 4R/c_m + 2R/c_g$ corresponding to multiple reflections within the sphere. Perfect matching of the ground to air is responsible for the additional structure in the IDFT, which tends to disappear in imperfectly-matched, lossy soils (see next two figures).

In each of Figs. 5 to 7, the upper left plot gives the magnitude and phase of the electric field E_x as a function of frequency for the entire scattered field; the middle left plot gives just the r-mode scattering. The lower left plot shows the least square error (LSE) and maximum error over the surface points as a function of frequency; in general, the LSE is about two orders of magnitude less than the maximum error. The right plot is the IDFT of the entire scattered field. Overlaid on this IDFT are the two characteristic times T_0 and T_1 , given by

$$\begin{aligned} T_0 &= 2d/c_g \\ T_1 &= T_0 + 4R/c_m \end{aligned} \quad (7)$$

In all three figures, these two characteristic times are a dramatic feature.

The T_0 and T_1 values correspond to the round trip time of a ray from a point directly above the mine traveling through ground and mine with velocities c_g and c_m , respectively. Because the mine has the well-measured dielectric constant of TNT and a characteristic size and shape (assumed here to be a sphere of radius R), the difference $T_1 - T_0 = 4R/c_m$ is specific to the mine target. Rocks, which have different dielectric constants and sizes, will give different pairs of time peaks. Once these time peaks are identified, the vertical position of the mine can be determined by estimating the ground dielectric constant (and thus the resulting ground propagation

Figure 6: Scattering of a TNT sphere buried in dry sand, with all other parameters identical to those of the previous figure. The frequency is plotted from 1 to 8 GHz in increments of 0.025 GHz and the LSE is significantly worse than in the case of air because the r-modes play a dominant role in the scattering. The IDFT of the total scattering signal possesses the characteristic times T_0 and T_1 as well as an additional time constant corresponding to $T_1 + 2d/c_g$. Although the sand is not very lossy, it is significantly mismatched to the air. No characteristic times greater than 2 ns are observed, unlike the scattering from the mine surrounded by air shown in the previous figure.

velocity), and multiplying by $T_0/2$. Since modal expansions of the target are relatively insensitive to small variations of mine shape and air/ground interface compared with burial depth and dielectric characteristics, the SAMM method efficiently identifies the salient features needed for mine detection.

5. CONCLUSIONS

A new algorithm is developed which finds all field components in the region of interest near a buried dielectric land mine by fitting spherical modes to all interfaces. This SAMM algorithm quickly and efficiently computes the frequency domain fields where they would be measured (on or near the ground surface in the vicinity of the suspected target) using the important physical aspects of the detection problem: size, aspect ratio, orientation, burial depth, and dielectric characteristics of the mine and surrounding soil.

Although a finely-sampled ultra-wideband frequency sweep requires too much computation to be performed in real time on currently available computers, the knowledge gained from studying several typical cases elucidates some of the important feature of wideband mine detection. Inverse Fourier transforming the scattered field frequency response gives a time signature with two characteristic peaks corresponding to burial depth and target size. These particular features are robust and uniquely characterize the target (though not necessarily the surrounding soil) with a single monostatic measurement. With multiple receivers and multiply-incident plane waves, more

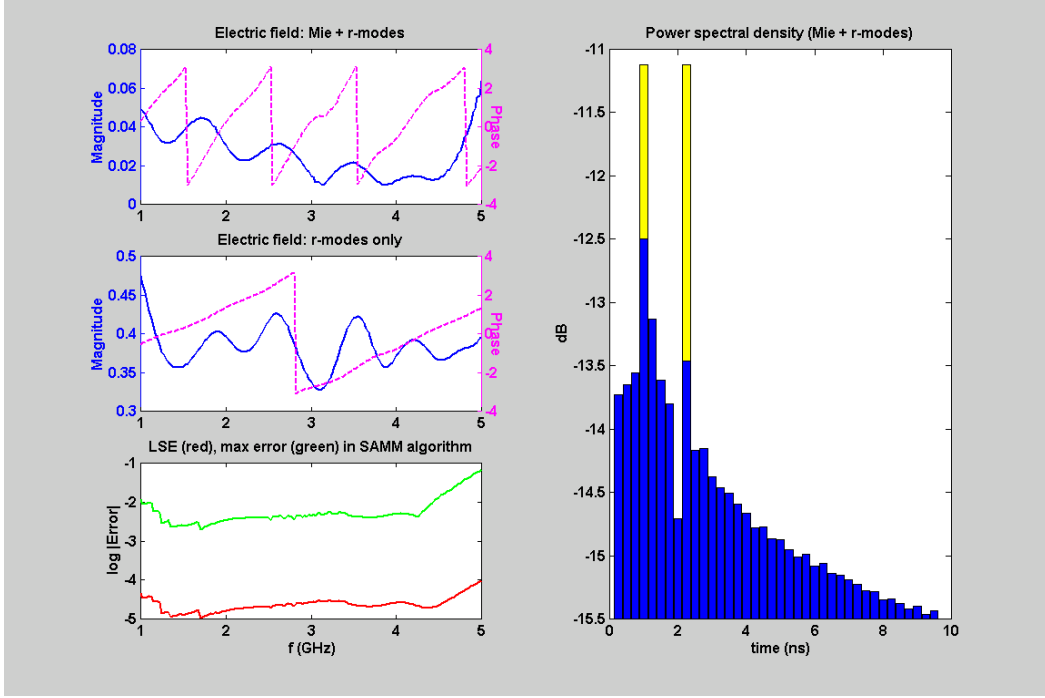

Figure 7: Scattering from a spherical TNT mine buried in Bosnian soil for 1 to 5 GHz in increments of 0.025 GHz, with other parameters equivalent to those of the previous two figures. In this case, the r-modes dominate because of the extreme mismatch between the soil, air, and mine. Errors at low frequency could be improved by making the area over which points are sampled on the plane larger, and errors at high frequency would be improved by using more modes. The IDFT of the total signal has only the two characteristic times T_0 and T_1 ; as in the case of sand, soil mismatch dampens the longer time constants.

independent information would be available to improve both detection and false alarm rates.

In addition, as long as the specular ground reflection is eliminated, these characteristic peaks become apparent regardless of the surrounding soil type, depth of burial, or even relative contrast between mine and ground. The peaks for a TNT mine can be clearly identified even when buried in soil with approximately the same dielectric constant, e.g., sand. The SAMM method is readily extended to oblique plane wave incidence, nonspherical targets, multiple targets and rough ground surfaces by specifying additional modal scattering centers. Work is also progressing on more sophisticated processing of the wideband frequency response and its IDFT beyond the simple identification of the time difference between characteristics peaks.

Abstract— A 2D finite difference frequency domain (FDFD) algorithm is used to verify new semi-analytic mode matching (SAMM) simulations of scattered fields resulting from plane waves incident on a random rough dielectric half-space containing a buried dielectric target. The SAMM algorithm uses moderately low-order modal superpositions of cylindrical waves, each of which satisfies the 2D-Helmholtz equation in its appropriate region (air, ground, or mine) and then matches all nonzero electric and magnetic field components at each interface by least squares fitting.

For smooth ground, coordinate scattering centers (CSCs) are chosen at the mine center and at its image above the plane to model scattering. For random rough ground, additional CSCs are located within the rough layer. Excellent agreement between 2D-FDFD and the two dimensional version of SAMM is observed, with 2D-SAMM being at least an order of magnitude faster; 3D-SAMM is estimated to be four orders of magnitude faster than 3D-FDFD, with drastically reduced memory requirements.

Keywords— GPR, mine detection, dielectric target imaging, modal analysis.

I. INTRODUCTION

A NEW 3D semi-analytic mode matching (SAMM) algorithm has been described previously [1], which is particularly adept at finding the scattered near fields from buried dielectric objects (e.g. antipersonnel land mines). Here, we validate the 2D version of SAMM for scattering from a 2D buried cylinder by comparing it to a 2D finite difference frequency domain (FDFD) simulation. We also extend SAMM to cases where the ground has a random rough surface, a topic of considerable interest [2,3]. We consider only normally-incident TM plane waves scattered from buried mines with circular cross-section, though oblique incidence and modestly irregular mine shapes are easily handled by SAMM. Three-dimensional rough surface scattering is more computationally difficult both for SAMM and FDFD methods, so we focus here on the simpler 2D geometry from which useful physical insights can also be extracted.

II. SEMI-ANALYTIC MODE MATCHING

For 2D cylindrical geometry having no variation along z , the TM electric and magnetic fields ($H_z = 0$) may be described by the vector Hertz potential $\mathbf{\Pi} = \hat{\mathbf{z}}\Pi_z(\rho, \phi)$ obeying the scalar wave equation $(\nabla^2 + k^2)\Pi_z = 0$, where

∇^2 is the 2D cylindrical Laplacian and k is the wave number in the medium of interest [4]. A modal expansion of Π_z is given by:

$$\Pi_z(\rho, \phi; k) = 1/k^2 \lim_{N_{\max} \rightarrow \infty} \sum_{n=-N_{\max}}^{N_{\max}} C_n F_n(k\rho) \exp(-in\phi) \quad (1)$$

where C_n is the cylindrical mode coefficient (units of electric field) and $F_n(kr)$ is a Bessel function of order n . With judicious use of the Bessel recurrence relations, we can find the Cartesian field components, *each of which must also satisfy the scalar wave equation*, in terms of the cylindrical modes of (1):

$$E_z = \lim_{N_{\max} \rightarrow \infty} \sum_{n=-N_{\max}}^{N_{\max}} C_n F_n(k\rho) e^{-in\phi} \quad (2)$$

$$H_x = \lim_{N_{\max} \rightarrow \infty} \sum_{n=-N_{\max}}^{N_{\max}} \frac{(C_{n-1} + C_{n+1})}{2i\eta} F_n(k\rho) e^{-in\phi} \quad (3)$$

$$H_y = \lim_{N_{\max} \rightarrow \infty} \sum_{n=-N_{\max}}^{N_{\max}} \frac{(C_{n-1} - C_{n+1})}{2i\eta} F_n(k\rho) e^{-in\phi} \quad (4)$$

where η is the wave impedance. To be useful numerically, (2)–(4) must be truncated at $n = N_{\max}$, a finite (small) integer. For an error of -290 dB (about machine accuracy) at 3 GHz, plane wave decomposition in dry sand [5] ($\epsilon_g = 2.55(1 + i0.01)\epsilon_0$) and Bosnian soil from the test site Alicia [6] ($\epsilon_g = 8.82(1 + i0.13)\epsilon_0$) requires 24 and 32 modes, respectively.

Equations (2)–(4) are applied to each region (air, ground, mine) where we expand the modes with respect to convenient coordinate axes. We locate these coordinate scattering centers (CSCs) so modal expansions will converge for small values of n ; in general, we place CSCs everywhere waves appear to originate.

Fig. 1 shows the geometry of a cylindrical mine with circular cross-section of radius R buried a depth d below the nominal surface of a random rough ground plane. Because there is no variation along z , the rough surface contour is actually a series of randomly-spaced, rounded grooves extending infinitely far in the $\pm z$ direction. The figure also indicates schematically how modes are defined in each region. For geometries which include an infinitely-extended ground plane, CSCs are chosen at *both* the mine and its image above the plane, in analogy with

Fig. 1. A dielectric cylinder with radius R is buried d meters below a rough ground surface. This particular randomly-generated surface has a ground-filled bump on the left and an air-filled pit on the right. Modes are given schematically in each of the regions where they apply, and are designated “J” or “H” depending on which Bessel function is necessary. Modes with no sub- or superscripts originate at the mine (C -coordinate system), while the primed modes originate at the image mine (origin at C'). Modes with 1 or 2 as subscripts originate at the CSCs C_1 and C_2 (there may be more surface CSCs if the rough surface has a small correlation length, and none if the ground is smooth). The incident plane wave (I) is reflected (R) and transmitted (T); this latter wave is decomposed into cylindrical modes (C), which lead to Mie scattering modes (A , T) [see text]. These Mie modes reflect and refract at the ground plane, leading to rescattering or r-modes, valid in their respective domains as shown. For the simpler case of a flat planar boundary, we eliminate the scattering centers C_1 and C_2 , and only the r-modes $\{r, q, q', t, t'\}$ remain.

image techniques routinely used for analyzing antennas over perfectly-conducting ground planes. For a smooth air/ground interface, this single image is sufficient to describe the scattering. For a rough surface, the bumps and depressions on the surface will each act as scattering centers, particularly in the case where the size of the defects is comparable to the size of the mine. In this case, we add CSCs at each place on the plane surface where rescattering is expected with the following procedure: (1) create a reflection of the rough surface about the nominal smooth ground surface making linked “bubbles” containing either air or ground, (2) put CSCs along this nominal plane in the center of each defect, and (3) choose modes within and without the “bubbles” which behave appropriately; i.e., use Bessel functions of the first kind $J_n(k\rho)$ for regions which include the CSC or to expand a plane wave, and use outwardly-propagating Hankel functions $H_n^{(1)}(k\rho)$ for regions which do not include the CSC and which must obey radiation conditions far from the scatterer.

Analytic (modal) Mie solutions for a dielectric mine of circular cross-section buried in infinite ground [4] describe unperturbed scattering with the coefficients A_n and T_n shown in Fig. 1. These Mie modes are then perturbed by the actual half-space ground with its random rough surface, leading to rescattering (r-modes) which come from all the multiple interactions between the mine and plane. We truncate r-modes originating at the mine, its image, and the rough surface at N_m , N_m , and N_s , respectively. The coefficients of these r-modes are found by locating N_{surface} points along the air/ground and mine/ground interfaces and reconstructing E_z , H_x , and H_y at each point using (2)–(4). The mode coefficients that best fit the three boundary conditions (one for each nonzero field component) at each of the N_{surface} sampled surface points are found using least squares techniques. We may test the final solution in two ways: (1) by demonstrating convergence of the nonzero fields to stable values as more modes are chosen, and (2) by comparing fields to those generated by established methods like FDFD or the moment method for identical geometries.

III. RESULTS AND CONCLUSIONS

In all simulations, a 3 GHz TM plane wave was normally incident on a 5-cm radius TNT mine having circular cross-section and buried 5 cm below the nominal ground surface of dry sand. For the SAMM algorithm, $N_{\text{max}} = 25$; the 35-cm planar surface and mine surface were both sampled with 600 points. FDFD simulations had a grid spacing of 1/12 cm corresponding to 441×420 grid points. For a smooth surface, the SAMM algorithm performs exceptionally well, exceeding the accuracy of the FDFD simulation after $N_m = 6$, as shown in column 3 of Table I. Column 4 compares the SAMM simulations to the most accurate case shown in the table: SAMM($N_{\text{max}} = 12$). SAMM(6) is about 16 times more accurate than the FDFD simulation, which has about 0.126% average error (attributable to discretization). The SAMM simulation took 3 [SAMM(1)] to 6 [SAMM(12)] min. on a Pentium-based personal computer, while the FDFD simulation took 45 min., almost an order of magnitude longer, and required the huge memory allocation of 0.93 million nonzero sparse matrix elements. By contrast, SAMM(6) required singular value decomposition of a 3600×65 element dense matrix.

The rough surface used for the SAMM and FDFD simulations is given in Fig. 2, and the magnitude of E_z is plotted in Fig. 3 for both the SAMM($N_m = 8$, $N_s = 4$) and FDFD simulations. The average error is 1.66% between methods, lies primarily near the rough surface, and is mainly attributable to SAMM. Table II shows how the average error varies with the mine/image modes number N_m and rough surface mode number N_s . As desired, excellent results are obtained by truncating r-modes at

TABLE I

COMPARISON OF SAMM AND FDFD FOR SMOOTH GROUND SURFACE

The average least squares error (LSE) on the smooth plane is computed for SAMM simulations as a function of r-mode truncation integer N_m . In addition, the SAMM simulations are compared both with a finely-gridded FDFD simulation and with the best SAMM simulation in the table, SAMM(12).

Smooth Surface, Average Error

Fig. 2. Geometry of the mine and random rough surface. The rough surface is generated by creating a coarse grid with spacing equal to 7 cm, the correlation length. Each grid point is randomly assigned a height from a normal distribution having a 1 cm rms surface height. Surface points are found by spline interpolation to the coarse surface grid.

many fewer than the $N_{\max} = 25$ modes required for accurate plane wave expansion. Increasing N_m appears to affect the error more sharply than increasing N_s , leading to the conclusion that fewer scattering modes need be kept from CSCs placed at the rough surface. Since these are the modes that add combinatorially, we expect that 3D-SAMM algorithms will prove quite tractable.

The 3D-SAMM would require about 6 times as many modes and 30 times as many surface points, corresponding to 200 times the memory and 1000 times the CPU time of

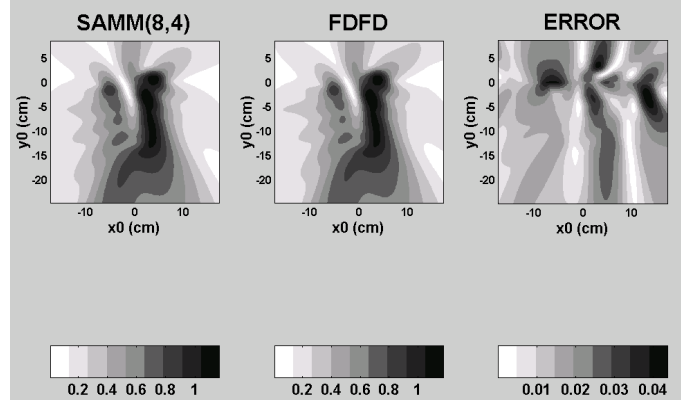

Fig. 3. $|E_z|$ plotted in the x - y plane for both SAMM(8,4) and FDFD using the rough surface of Fig. 2. The error is less than 4% and averages 1.66%.

TABLE II

COMPARISON OF SAMM AND FDFD FOR RANDOM ROUGH SURFACE

SAMM simulations having N_m modes for the CSCs centered at both the mine and image mine and N_s modes for each CSC centered within the rough surface are compared with a finely-gridded FDFD simulation.

Rough Surface, Average Error					
$N_m \backslash N_s$	0	1	2	4	8
1	0.192	0.121	0.0953	0.0830	0.0811
2	0.147	0.0850	0.0797	0.0768	0.0764
4	0.0672	0.0257	0.0232	0.0222	0.0224
8	0.0234	0.0171	0.0169	0.0166	0.0169

2D-SAMM; by contrast, 3D-FDFD needs more than 1000 times the storage and 10^6 times the CPU requirements of 2D-FDFD. Although SAMM is more difficult to program than FDFD and cannot currently model fine-scale roughness, the favorable scaling from 2D to 3D in the SAMM algorithm makes this new method worth pursuing.

Abstract:

The problem of scattered and transmitted electromagnetic wave distortion by random rough ground surfaces can be reduced by using a lightweight dielectric matching layer. For mine detection applications, it is essential for this layer to be lightweight, low loss, readily conformable, and adaptable to different soil types.

Arrays of metal-coated plastic spheres act as lossless artificial dielectrics with impedance determined by the volume packing fraction. By controlling the thickness of insulator surrounding each sphere, a close-packed array with the dielectric properties of soil can be created inside a compliant rolling bag that will conform to the rough surface of the ground. Since this artificial dielectric is matched to the soil, the ground surface interface is “softened”, without an abrupt transition from soil to air. Signals transmitted and received by GPR antennas immersed in the artificial dielectric within the bag will not be corrupted by ground surface clutter. Alternatively, an artificial dielectric layer on the ground with a planar air interface could be used to ensure that the surface reflection is a constant, well-calibrated signal.

Computational models indicate complete removal of the ground clutter, even with occasional gaps between the artificial dielectric and the ground. Experimental studies with swept-frequency measurements and impulse GPR indicate that using this dielectric layer matching to a rough loamy soil ground surface results in signals that are practically indistinguishable from those of an equivalent layer of the same type of soil.

Keywords: mine detection, artificial dielectrics, ground-penetrating radar, coupling, impedance matching

Introduction

A major challenge of radar detection of near-surface buried objects—such as land mines—is to distinguish the signals scattered from targets as opposed to the ground surface. In the particular case of nonmetallic mines, the contrast between the mine and the surrounding soil is often lower than between the soil and the air above it; and the clutter signal from a rough interface is often much stronger than the target signal from the mine. For more deeply buried targets, it is possible to reduce this clutter by time gating a short duration radar signal. However for targets buried at depths comparable to the height variation of the rough surface, this gating is not feasible. While it is possible to reduce the ground scattering clutter by attempting to characterize it using statistical methods [1-3], or illuminate the ground with an inclined plane wave and measure the backscattered signal [4,5], a more direct way to is to directly eliminate the surface roughness with an artificial matching layer.

Artificial Matching Layer

The purpose of an artificial layer is to fill the voids and lessen the effects of bumps in the ground surface with a medium that electromagnetically resembles the soil. To reduce clutter, it is more important to “soften” and “planarize” the interface than to act as an impedance transformer between the soil and the air. If the effective interface at the top of the layer is planar, and its impedance is known, the reflection of waves from the interface are easy to account for, and their contribution to clutter can be effectively subtracted. For example, this reflection from the layer top could be measured as part of the radar calibration procedure, or calculated numerically. Alternatively, the entire antenna could be immersed in a compliant bag filled with the artificial dielectric material, so that there would be no air interface.

Figure 1 schematically shows how this configuration might look, with a thin, but tough plastic bag filled with a lightweight material that simulates soil. It is obviously important to ensure that the material be light enough to avoid triggering mines, and that the material be loose enough to reconfigure itself as the bag rolls along the ground.

Conducting spheres that are spatially separated have been used as artificial dielectrics (AD) for many years [6]. However, solid metal balls are too heavy for this use, and separating them in a fixed matrix is clearly infeasible. Instead metal-coated plastic balls could be used. These lightweight “beads” are available as decorative craft items. An additional benefit is that these beads are lacquered or plastic coated with an insulating layer that serves to isolate them for one another.

Figure 1: Geometry of the artificial dielectric matching layer, used to reduce the clutter effects of random rough ground for GPR mine detection.

Simulation of Imperfect Void Filling

One concern with using an array of discrete objects in a bag as an artificial layer is the possibility of occasional gaps between the soil and the matching medium. The extent of this imperfect filling can be predicted numerically.

Using the FDTD method for dispersive soil [7], we computed the distorting effects of occasional air voids (depicted in Figure 2). A modulated TM Gaussian pulse, originating at a point 35 cm above the rough surface of Puerto Rican clay loam with a metallic target buried 10 cm below the nominal surface, was modeled with and without the AD.

Figure 3 shows the total field at the same time instances for the three comparative cases. At left, the moderately rough ground surface, with ± 5 cm height variation causes enough

wave scattering to completely obscure the buried target. The incident cylindrical wave and the transmitted wave are visible, as is the lack of field within the mine. Even for this strong scatterer, the ground clutter dominates. The second and third plots show the reduction in clutter when an AD is used. With no air voids (center), the incident field exists solely in the AD and soil. The interface is,

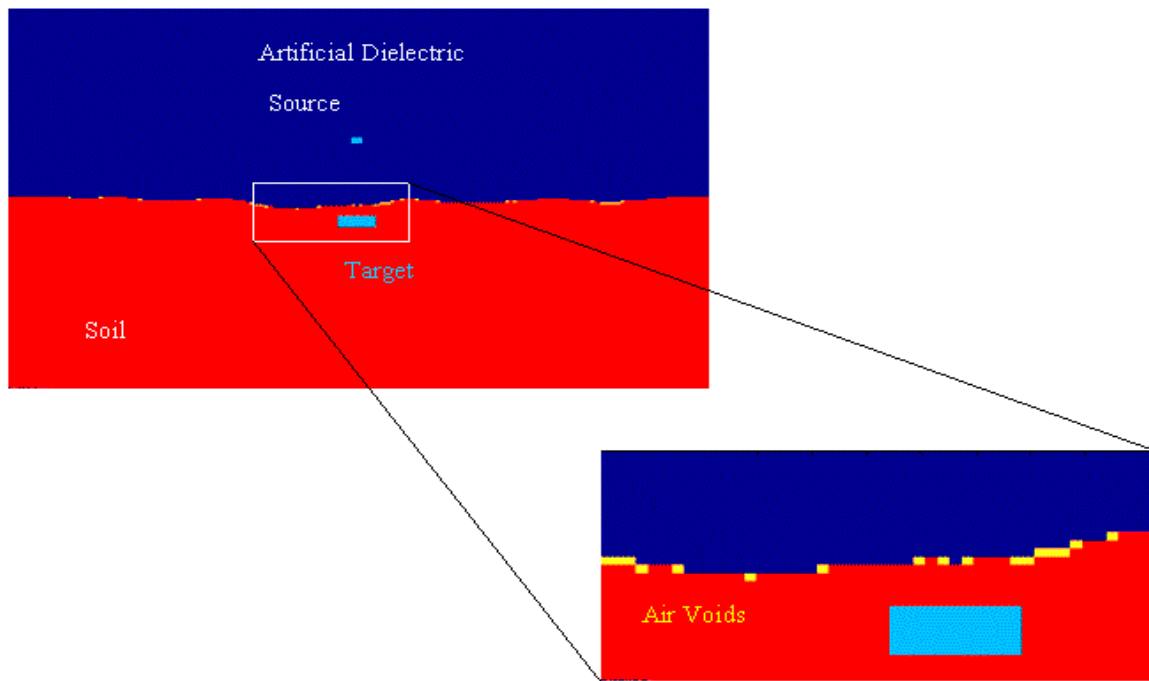

Figure 2: Modeled geometry with air, dispersive clay soil, and occasional air voids

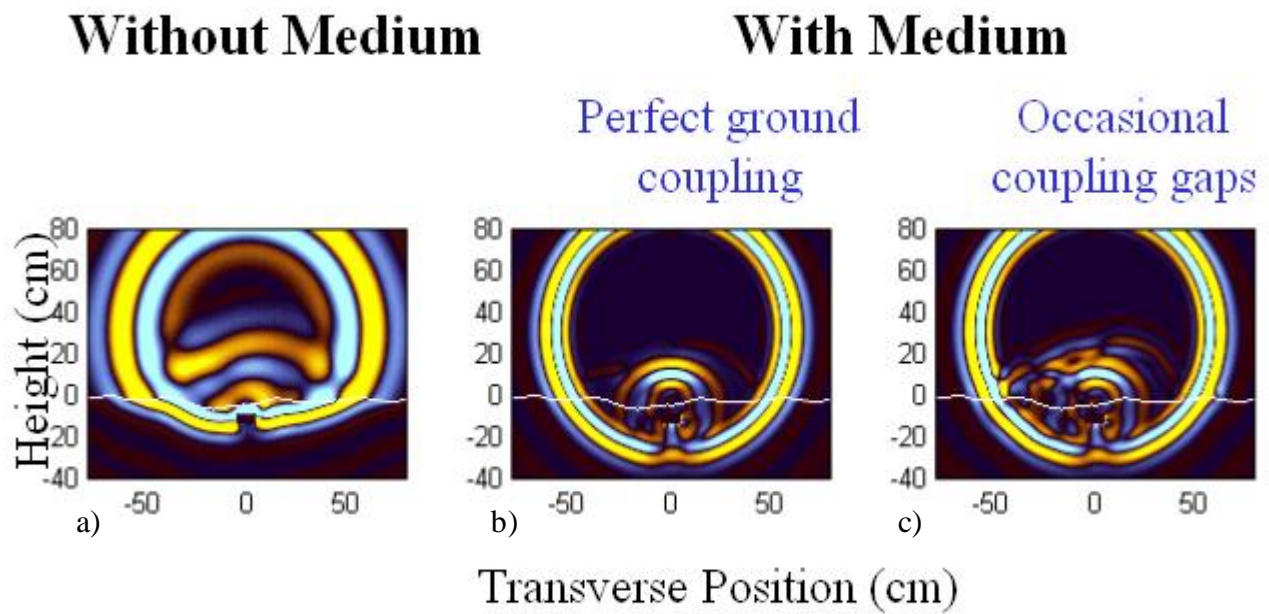

Figure 3: Comparison of modeled field a) without AD matching layer, b) with matching layer perfectly conforming to ground surface, and c) with realistic layer with air gaps

for all practical purposes, undetectable. The wave scattered by the target is clearly visible as the second smaller radius circle centered at the target. Compared to the first case, it is quite straightforward to identify which signal originates at the mine. In the third plot, the gaps of Figure 2 result in some clutter from the imperfectly matched interface. However, these scattered fields are small compared to those of the mine target.

Artificial Dielectric Impedance Calculation

The effective impedance of an array of conducting spheres is dependent on the geometry of the array, and the proximity of the spheres. The sphere separation can be computed in terms of the volume packing fraction of spheres in space. For simple cubic (sc) packing, with a sphere of radius r on each corner of a unit cube, the volume occupied by the eight sphere octants that lie within the cube is $4/3\pi r^3$, which is also the packing fraction. The maximum packing fraction occurs when $r = 1/2$, with a value of about 0.52. For a face centered cubic (fcc) packing, in which there are spheres centered on the cube corners and the centers of the cube faces, the volume (and hence packing fraction) within the six hemispheres and eight octants that lie within the cube is $16/3\pi r^3$. The maximum sphere radius in this case is one-quarter of a face diagonal, or $\sqrt{2}/4$, leading to a maximum packing fraction of 0.74.

The calculated impedance of an array of conducting spheres, as a function of packing fraction for sc and fcc can be approximated by the formulas [6]:

$$\left. \begin{array}{l} \epsilon/\epsilon_0 \\ \mu/\mu_0 \end{array} \right\} = 1 + 3p/A(p)$$

where

$$\begin{aligned} \text{For sc: } A(p) = & -1/R_1 - p + 1.3047R_3p^{10/3} + 0.0723R_5p^{14/3} \\ & - 0.5289R_3^2p^{17/3} + 0.1526R_7p^6 \end{aligned}$$

$$\begin{aligned} \text{For fcc: } A(p) = & -1/R_1 - p + 0.0753R_3p^{10/3} + 0.2420R_5p^{14/3} \\ & + 0.0558R_3^2p^{17/3} + 0.0231R_7p^6 \end{aligned}$$

and

$$R_n = \begin{cases} -1 & \text{for effective dielectric constant} \\ n/(1+n) & \text{for effective magnetic permeability} \end{cases}$$

Figure 4: Dependence of effective dielectric constant and magnetic permeability of AD in terms of volume packing fraction p .

These formulas are plotted in Figure 4, showing that the sc packing has slightly greater effective dielectric constant and lower permeability than that of the fcc packing, but that a higher packing fraction is possible with fcc. In practice, we would expect that random distributions of spheres would fall between the two sets of curves. For a dense random packing of thinly insulated spherical beads, we might expect a relative impedance as high as $\sqrt{(0.25/10)}$, or about 0.16 times the impedance of free space. This matches a dielectric constant of 39 in a non-magnetic ($\mu = \mu_0$) medium, much greater than most soils.

As most mine detection systems operate over several frequencies at once, it is important that the AD layer match over a wide frequency band. Figure 5 shows the reflection coefficient as a function of

Figure 5: Computed reflection coefficient for AD/soil interface with normal incidence for four discrete frequencies, as a function of packing fraction p . The soil is Puerto Rican clay loam with 10% moisture and 1.6 g/cc density.

packing fraction for various frequencies for a planar interface between AD and frequency-dependent lossy soil. As long as the wavelength is large compared to the diameter of spherical conductors in the AD array, its bulk dielectric constant is independent of frequency. In addition, the AD is lossless, so the reflection coefficient increases as the loss tangent increases. Figure 5 indicates that even for fairly dispersive soil, a good wide-band impedance match is possible.

Considering a typical range of soil dielectric constants from 2.5 (dry sand) to 20 (20% moist clay loam), it is feasible to match the impedance using one of as few as three or 4 well-chosen ADs. Dividing the range into three dielectric regions centered at constants 3.33, 7.3, and 16.0 would introduce a maximum normally incident reflection coefficient of 0.098. For the four-region division with dielectric constants 2.98, 5.22, 9.13, and 16.0, the maximum reflection coefficient is 0.070. The range of dielectric constants covered in each region is shown in Figure 6. The boundaries of each of these regions are determined by equating the ratio of the central value to the boundary value (or its inverse).

Figure 6: Segmenting the typical range of soil dielectric constants into three or four regions with the same maximum reflection coefficient: 0.098 (top), and 0.070 (bottom).

Experimental Realization of Artificial Dielectric

Using just freely flowing insulated conducting craft beads for a matching layer would produce the maximum effective AD dielectric constant. To match to a particular soil requires increasing the spacing between the beads. Alternatively, it has been found that by introducing small air-filled plastic balls to the beads reduces the volume packing fraction, albeit non-uniformly. As long as the balls are fairly uniformly distributed amongst the beads, and their diameters are small compared to the smallest

wavelength, they can be viewed as an array of lower dielectric constant spheres in a higher dielectric constant background: sort of a reverse artificial dielectric. The net effect is to reduce the overall bulk dielectric constant.

Several sizes of polypropylene balls were used to adjust the packing fraction and effective dielectric constant: 20, 10, and 6 mm diameter. Each AD mixture of beads and balls was tested in a cylindrical cavity by comparing its S-parameters to those of soil. In order to prevent direct interaction with the coaxial probe inserted into the cavity, the bottom portion was filled with paraffin. Although this complicates the direct wideband measurement of the dielectric constant of the material under test, it does provide for direct impedance comparisons across the entire frequency band of interest.

Relatively good performance from 700 MHz to 1.7 GHz was obtained using several mixture combinations. The S_{11} response is presented in Figure 7 for various mixtures compared to 15% moist clay loam. Also shown is the response for dry sand, which is quite different.

The S_{21} measurements for a transmitter/receiver probe pair inserted in a soil-filled tank with the AD or soil filling an intervening region gave similar well-matched results.

Figure 7: S_{11} measurements of a cylindrical cavity partially filled with: soil (dark solid line), AD with 20 mm balls (o), 10mm balls (+), or sand (--).

Impulse Radar Experiments using AD Matching Layer

With a good impedance match over the frequency range of an impulse radar, the final step is to compare the time domain signals scattered from smooth, roughened, and AD matched rough soil. For this experiment, the impulse radar used was the Geo-Centers, Inc. EFGPR with TEMR antennas [8]. Two antennas—one acting as the transmitter, and the other the receiver—were positioned next to one another roughly 2 meters away from the surface of the tank of sifted clay loam soil. A 900 ps single pulse was fed to the transmitter, and the waves scattered from the soil surface was measured by the receiver for various cases.

First, the soil surface was raked as flat as possible, providing a planar half-space interface. The scattered field was measured. Next, soil was removed down to about 3 inches in several spots (corresponding to a standard deviation of about 1 in. relative to the mean level) and set aside. The rough surface signal was measured. The depressions were next filled with the AD mixture of beads and 20 mm polypropylene balls in the volume ratio of 1.73 to 1, and the top surface smoothed. A photograph of this configuration appears in Figure 8. The field scattered from this smoothed surface was measured, and the AD was twice removed, replaced, and the signal remeasured. Finally, the AD was completely removed (facilitated by using the plastic sheet seen in Figure 8), and the original removed soil was replaced and smoothed, and the scattered signal measured.

Figure 8: Soil test tank, with rough surface “smoothed with AD composed of 6mm insulated conducting beads and 20 mm balls, in a volume ratio of 1.73 to 1.

The measured results for the six test cases are presented in Figure 9. Five of the six traces appear to have almost the same behavior, with the greatest variation at late times, 3.5 ns after the first arrival. The sixth trace, corresponding to the rough soil surface without AD is significantly different, with as much as 0.3 ns delay relative to the flat soil surface. Although this delay may not seem like much, it can cause significant error in the processing of the radar signal. For example, at time $7.98\text{E-}8$, the rough surface clutter is negative, while the flat surface signal is positive with almost the same magnitude. Any clutter reduction using the wrong assumption of the ground surface would introduce 100% more error at this time point!

It is interesting to note that the time shift between the rough and smooth ground signals is not constant, indicating that there are multiple scattering effects occurring with this rough ground surface. This is why attempts at identifying and subtracting the ground reflected signal as a shifted copy of the flat ground signal does not always reduce ground clutter [2].

As is evident from Figure 9, the various AD placements repeatably form a well-matched layer to the rough surface soil. Although the response from the soil with the AD layer is not exactly the same as the original flat surface soil, its variations are comparable to the case of the original soil being replaced and resmoothed.

Figure 9: Time domain measurements of soil with flat surface, rough surface, and with added AD composed of beads and 20 mm balls in volume ratio 1.73 to 1.

Conclusions

An artificial dielectric, which maintains the approximate impedance characteristics of soil over a wide frequency range, has been developed and experimentally tested. Being flexible, lightweight, and with adjustable dielectric constant, this AD composed of insulated, metallized craft beads can be used in mine detection applications where it is important for this layer to conform to ground surface variations while exerting minimal pressure on the ground.

The AD can be used as a rough ground surface smoothing layer with a planar top surface, or as a medium to fill the entire space between the antenna and the ground. As a smoothing layer, the AD can effectively replace the random interface roughness that corrupts the GPR signal with hard to characterize clutter with an unchanging planar interface the effects of which can be easily identified and eliminated. Computational modeling has shown that even with imperfect filling of rough surfaces, the clutter reduction is significant.

The effective impedance of the artificial dielectric is easily controlled by adjusting the volume ratio of beads to non-conducting polypropylene balls. Only three or four types of bead/ball AD mixtures are needed to match the entire range of most soil dielectric constants with reflection coefficients less than 10%.

Experiments with fielded impulse GPRs indicate that the AD layer matches to rough soil surfaces about as well as the same soil does.

- **Frequency Domain Results**
- **Time Domain Results**
- **Summary**

Land Mine Detection Problems

- No single type of “target”
 - 647 types of mines (i.e. size, shape, material - plastic)
- Ground is different from country to country
 - ground isn't flat:
 - rough soil surface may also randomly scatter much of the transmitted sensing signal and be a significant source of detection noise ----> this is a MAJOR problem**
 - soil type is never known (inhomogeneous soil, moisture content, etc.)
 - it may also have buried rocks, moisture pockets, tree roots, and bits of scrap metal especially if a former battlefield
- Burial depth of mine in ground varies
 - exposed
 - just under surface
 - shallow burial
 - deep burial

} Radar not effective

Humanitarian Demining Mission

- **Finding anti-personnel land mines:**
 - small “targets”: ~ 10 cm diameter
 - non-metallic: ~ .5 gram metal firing pin
 - not deeply buried < 15 cm deep
- **Ground-Penetrating Radar (GPR) ----> one approach for shallow penetration**
 - distinguish mine based on the shape of anomaly in soil
 - time domain or frequency domain
 - inexpensive to build
 - very susceptible to natural clutter

For GPR applications, the “target” is characterized not only by the inherent properties of the buried object and soil but also by the effects of the air-ground interface

Finite Difference Frequency Domain Technique

FDFD

- **Computational tool for simulating the scattered wave distribution**
 - A direct solution of Maxwell's curl equations in the frequency domain
- **Permits accurate representation at each frequency**
 - random rough surface (ground roughness)
 - various target shapes
- **Appropriate for near-field scattering**

2-D FDFD Land Mine Simulation Cases

Parameters Varied (36 Cases Total)

- **TNT Mine:** $E_r = 2.9(1+0.001i)$
 - Circular (5 cm radius)
 - Elliptical (5 cm by 3 cm)
 - Rectangular (10 cm by 4 cm)
- **Ground Surface**
 - Smooth
 - Rough (avg. roughness = 1 cm, corr. length = 4 cm)
- **Ground Type**
 - **Dry Sand:** $E_r = 2.55(1+0.01i)$ at .5 GHz
 - **Bosnian Soil:** $E_r = 8.9(1+0.13i)$ at .5 GHz
- **Burial Depth of Mine in Ground**
 - 2.5 cm, 5 cm, and 10 cm
- **Frequency Bandwidth:** .5 to 5 GHz, 100 MHz steps
- **Time Domain Considerations:**
 - 341 receivers above mine (transverse position)
 - receiver observation heights: at interface, 2.5 cm and 5 cm above interface,

Note: Each FDFD simulation took 12 hours to run on an SGI Octane (output file = 100 MB)

Outline

- Background
- Frequency Domain Results
- • Time Domain Results
- Summary

Time Domain Signature Investigation

- The power spectral density of the reflected signal yields a time domain signature dependent of the soil characteristics as well as the burial depth and radius of the mine
- Two or more characteristic time peaks (T_0 and T_1) are observed suggesting that the ultra-wideband spectral radar response may yield particular advantages not exploited by currently employed detection systems
- The ultra wideband timing characteristic behavior is examined for three different heights at/above interface (i.e., at interface, 2.5 cm and 5 cm above interface) over the entire transverse distance and time
- This study determines the feasibility of detecting mine-like targets based on stepped-frequency GPR time signatures

Characteristic Times for Circular Target in Lossy Media

Land Mine (5 cm radius) Buried 5 cm Deep in Dry Sand with Smooth Air-Ground Interface

Characteristic Time Equations at Interface directly above mine

$$T_o = \frac{2d}{c_g}$$

$$T_1 = \left(\frac{2d}{c_g} + \frac{4R_{av}}{c_m} \right)$$

d = burial depth
 c_g = average soil wave velocity
 c_m = mine wave velocity
 R = average mine radius

Two-way travel times, T_o and T_1 , are timing peaks that directly correspond to the burial depth and target size if the dielectric constant of the land mine and soil are known a priori

Summary

- **Rough surface effects are a dominant scattering mechanism in the GPR detection of buried objects**
- **Frequency domain numerical modeling (FDFD) is a viable means of testing candidate sensing concepts on a wide variety of conditions**
- **Using the appropriate signal processing techniques, land mine identification using spectral timing peaks is a viable means to determine land mine burial depth and size**
 - **wideband processing enables time signatures that highlight invariance**
- **Application: stepped-frequency GPR radar**

Northeastern University

Guiding Principles

- **Basic Research**
 - Systems approach: optimize sensor configuration & combination, modeling, processing, and reconstruction
 - Establish quantifiable performance bounds
- **Combined Modalities and Algorithms**
 - Devise sensors with multiple physical effects
 - Fuse multiple sensor information
- **Support Theory with Real Measured Data**
 - Design the sensor configuration first
 - Control and understand data collection

Demining Mission

- **Humanitarian Demining: Find Anti-personnel mines**
 - Small targets: ~10 cm diameter
 - Non-metallic: ~0.5 gram metal firing pin
 - Not deeply buried < 15 cm deep
- **Target in real environment**
 - Inhomogeneous soil
 - Realistic, rough ground interface
- **Practical detection modalities**
 - Efficient
 - Low cost
 - Light weight
 - Robust/Flexible/Rugged
- **Develop modality to suit mine position in ground**

SDFMM for Two Penetrable Objects Buried under Random Rough Ground

“Steepest Descent Fast Multipole Method”

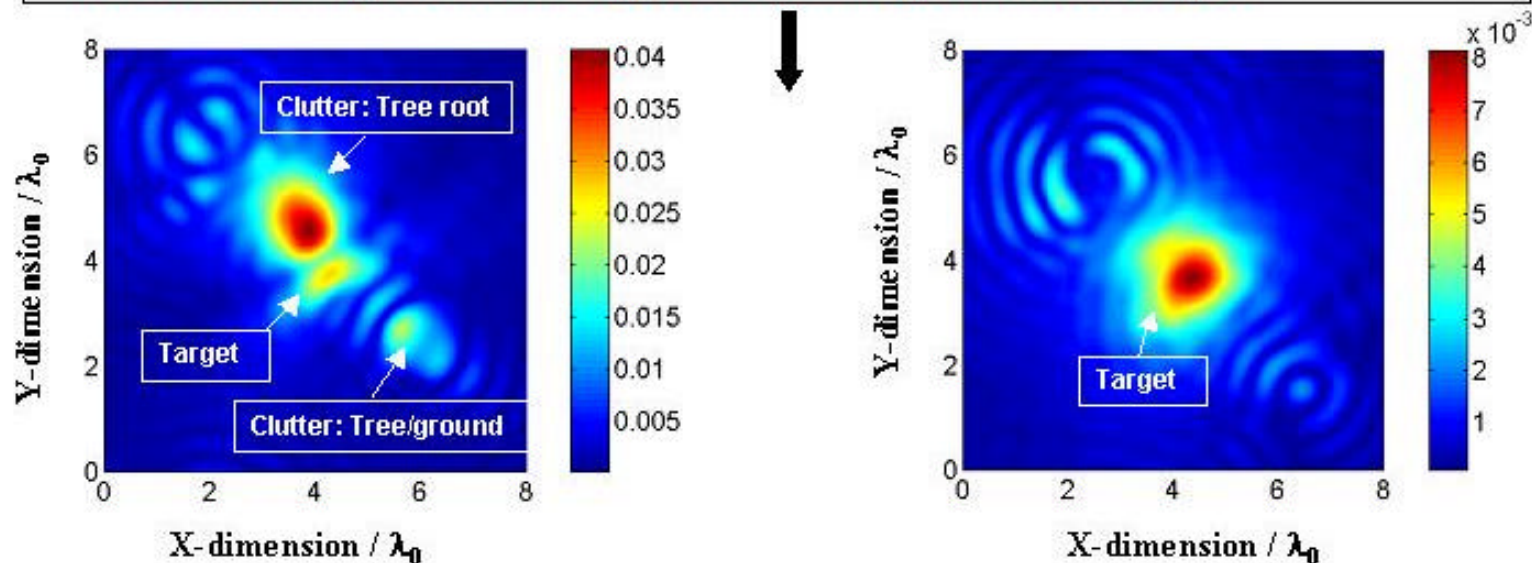

- 3-D Fast MoM Modeling
- Random rough ground.
- Near field computations.
- Target & Clutter objects.
- New integral equation formulations.
- Fast Multipole Method to solve for the unknown surface currents.
- Sources of Clutter: (1) Rough ground, (2) Second object.
- Parallel Implementation of the fast SDFMM computer code.
- Parametric investigations: target/clutter object shape, separation, location, multiple frequencies, Monte Carlo simulations.

Study of Mutual Coupling Effects of Multiple Buried Objects

Statistical average for clutter object is dominating that for the target: False Alarm.

Finite Difference Modeling Predicts Detectability and Aids in Sensor Design

- **Frequency domain (FDFD) suggests features for target discrimination.**
 - Point source and plane wave excitations possible
 - Soil inhomogeneities can be accurately modelled (loose soil)
 - 3-D implemented using sparse techniques with 50X speedup over FORTRAN
- **Time domain (FDTD) assists in characterizing and filtering rough ground clutter effects.**
 - 3-D model validated with measured data for GeoCenters TEMR element on outdoor test track
 - FDTD model for smooth or average surface reflection used to minimize surface clutter and enhance plastic mine target

Target Response

Total Response

Experimental Results for Conducting Bead Artificial Dielectric Matching Layer

- Lightweight Artificial Dielectrics can be made easily and inexpensively
- Wide range of soils permittivities can be matched with Artificial Dielectrics
- Response from rough ground smoothed with AD:
 - almost as good as undisturbed soil
 - just as good as if holes refilled with original soil
- Target signals greatly enhanced using AD
 - Rough ground clutter effectively suppressed
 - Target depth accurately determined

Subsurface Ultra Wideband Radar Probe Confirmatory Sensor

- Use frequency independent **Conical Spiral** antenna, adapted to lossy soil as probe inserted near target
- Illuminate target with 0.5 to 8 GHz circularly polarized wave
- Detect wideband spectral response with same, second, or above surface antenna
- Observe spacing between peaks in FFT signal which depend only on target composition and geometry

Comparison of Measured GPR Data with Flat and Rough 3-D FDTD Simulations: Ground reflection & target signal

GPR Signal Processing: Programmatic Overview

- **Basic philosophy:**
 - Combination of tractable physical models with sophisticated, statistical signal processing methods to make intellectually interesting advances that address real problems
- **Algorithmic work**
 - Recursive detection methods for array GPR data based on sequential hypothesis testing and modified ANOVA technique
 - Fusion of physics-based backprojection (F-K Migration) with min-entropy image restoration work to obtain robust GPR SAR auto-focus method for object localization
- **Validation: all on real data**
 - Detection method: NU and EG&G data
 - Localization: NU, DeTeC, NITTEK data
- **Continued effort work via Night Vision Forward Looking Program**

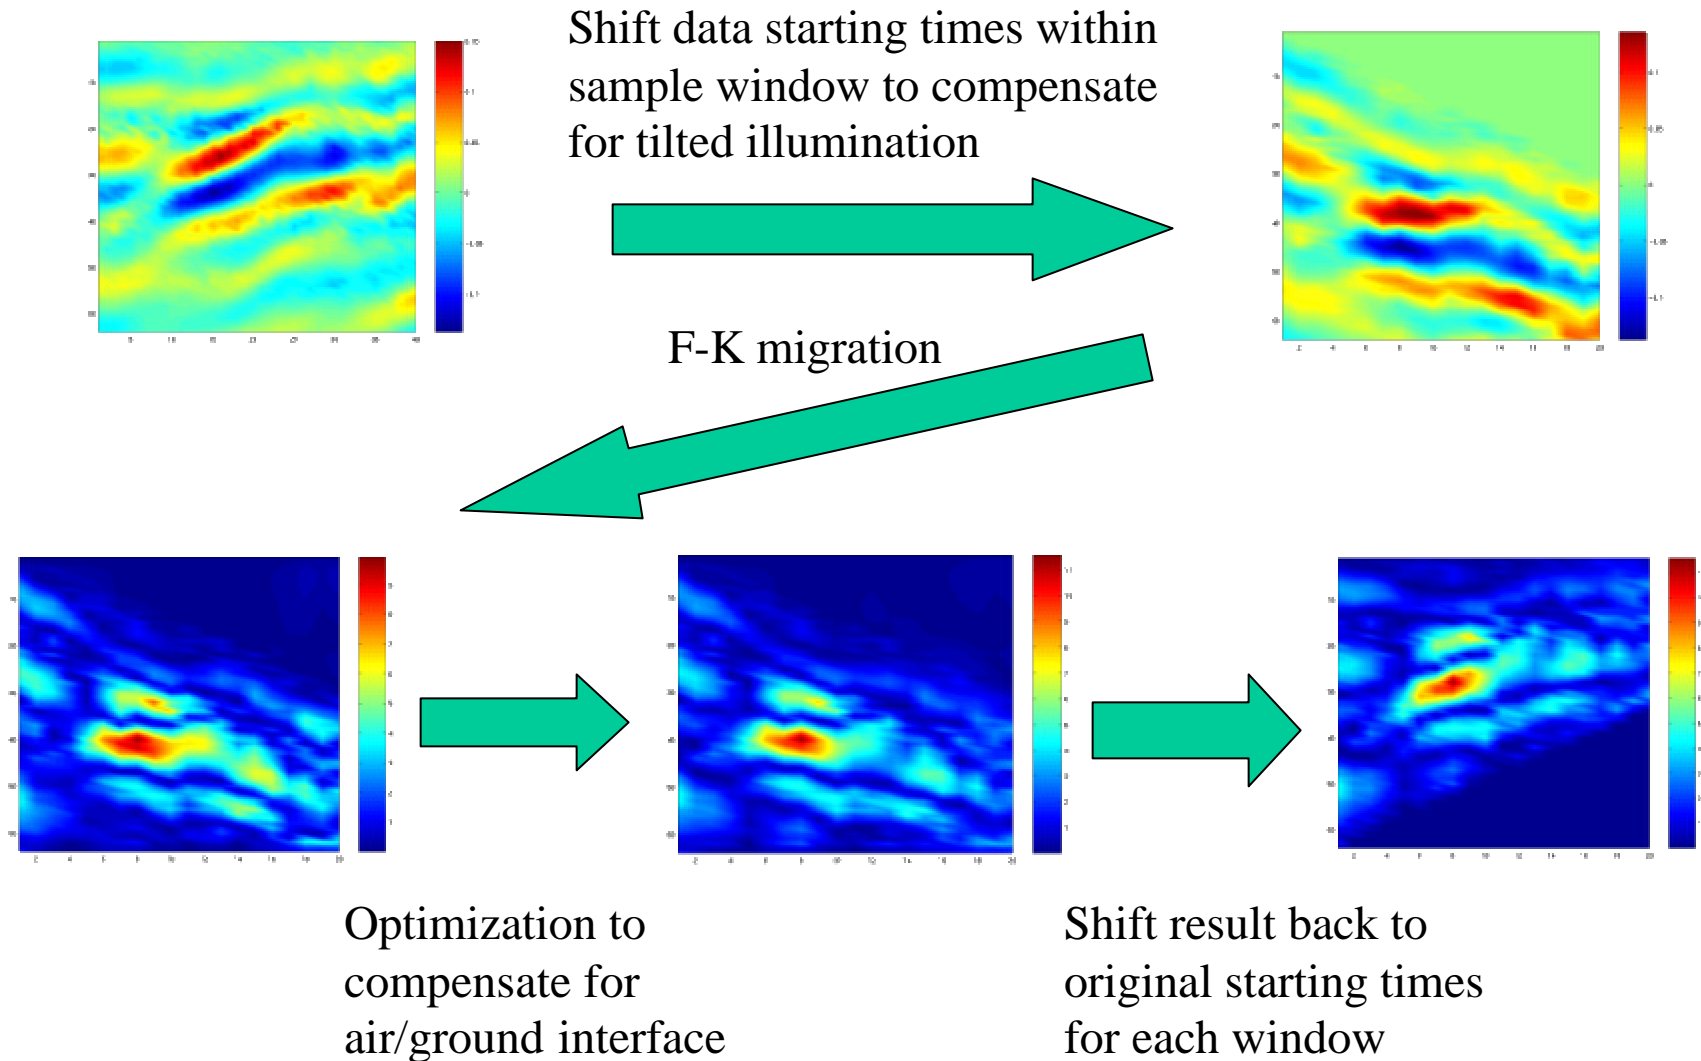

Matched Filter Processed GPR Signals

GPR Signal Processing: Accomplishments

- **Basic problem:**
 - Localization of buried targets from multi-monostatic and multistatic GPR data
- **Approach:**
 - Novel fusion of simple physics and solid image restoration in the form of entropy-regularized, F-K migration technique
- **Results:**
 - Strong localization ability demonstrated on real data sets from multiple sources (NU, NIITEK, DeTeC).

Measured NEU Data Processing with Optimized F-K Migration: PMN AP Plastic Mine

Measured Data: Wichmann Radar for M19 target

FK
result

Opt'ed
FK result

EMI: Programmatic Development

- **Philosophy:**
 - Simple, parametric physical models combined with “robustifying” processing schemes to arrive at novel methods for solving real problems
- **Algorithmic advances**
 - Optimal processing of data collected as a function of time, space, and frequency
 - Recursive detection methods designed to function progressively as the data are acquired
 - Batch data approach to object characterization robust to unknown orientation and location of object
- **Proof-of-concept level validation on real sensor data**
- **Transition to UXO problem via SERDP SEED grant**

EMI Track Scan

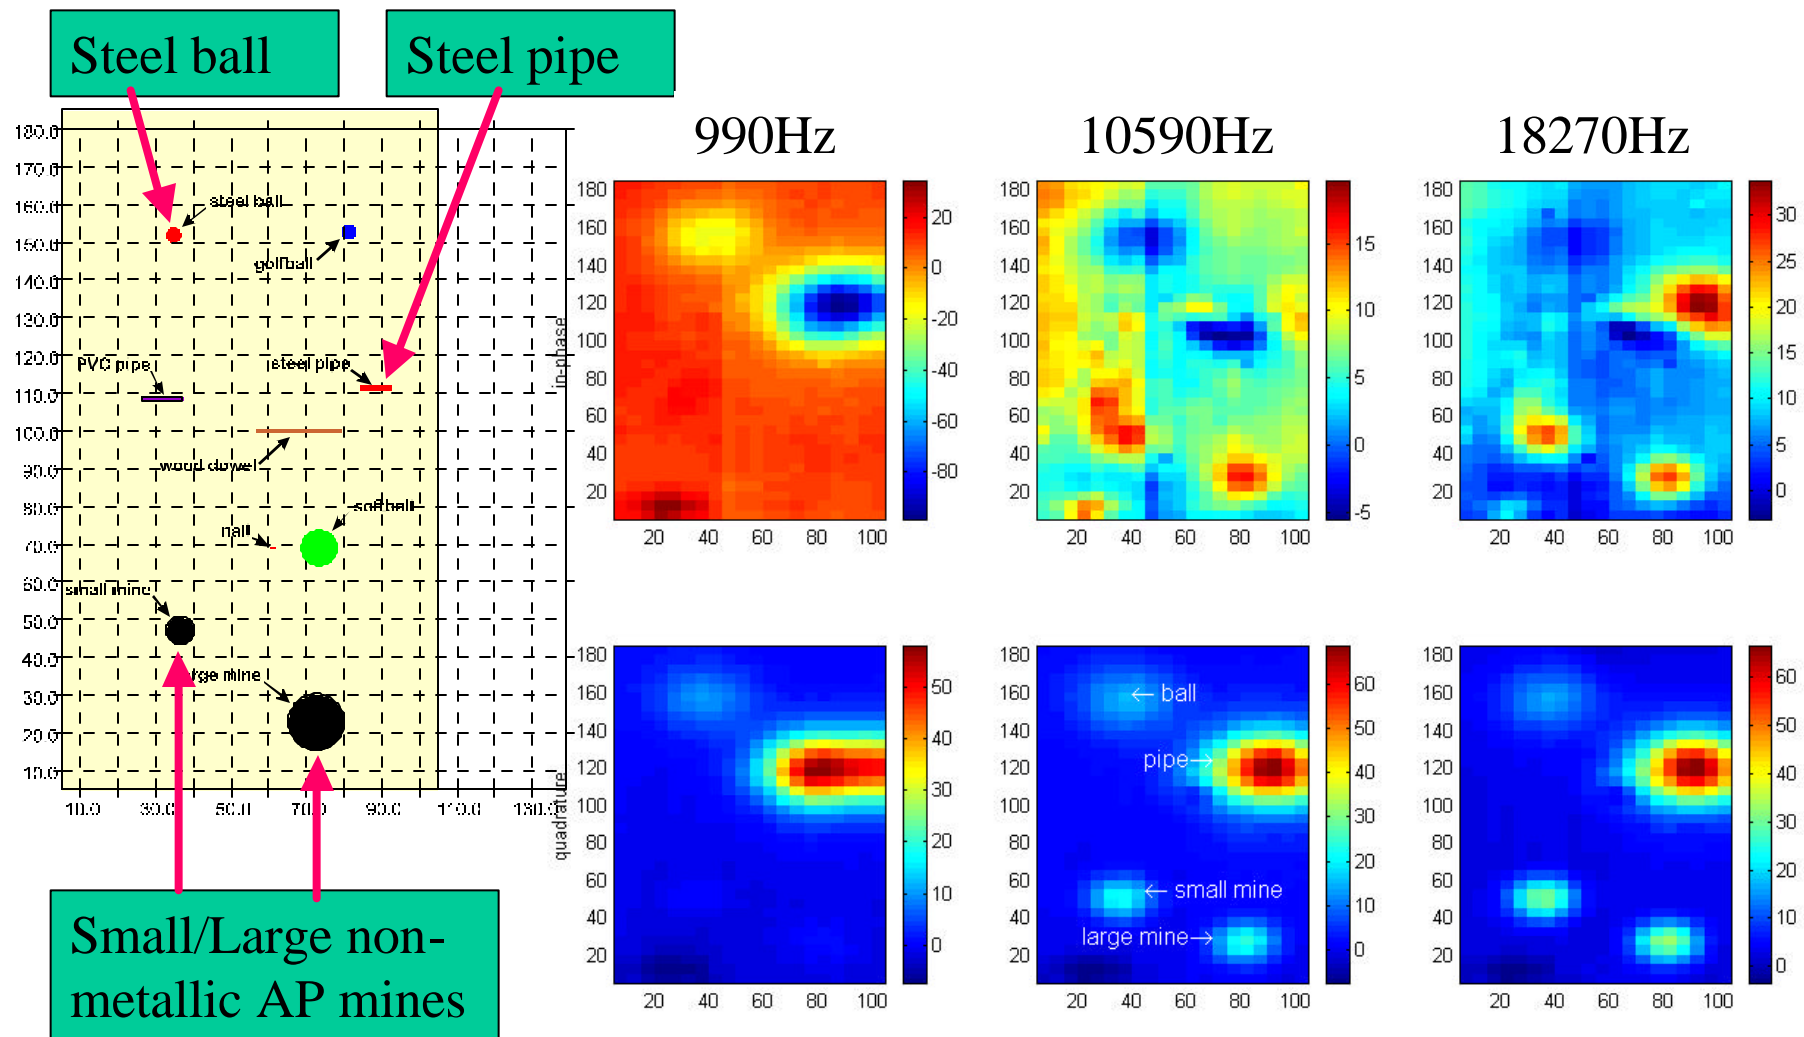

- Geophex GEM-3 EMI sensor
- Ten frequency bands sampled
- Full track scans at 6" resolution
- Detail target scans at 3" resolution

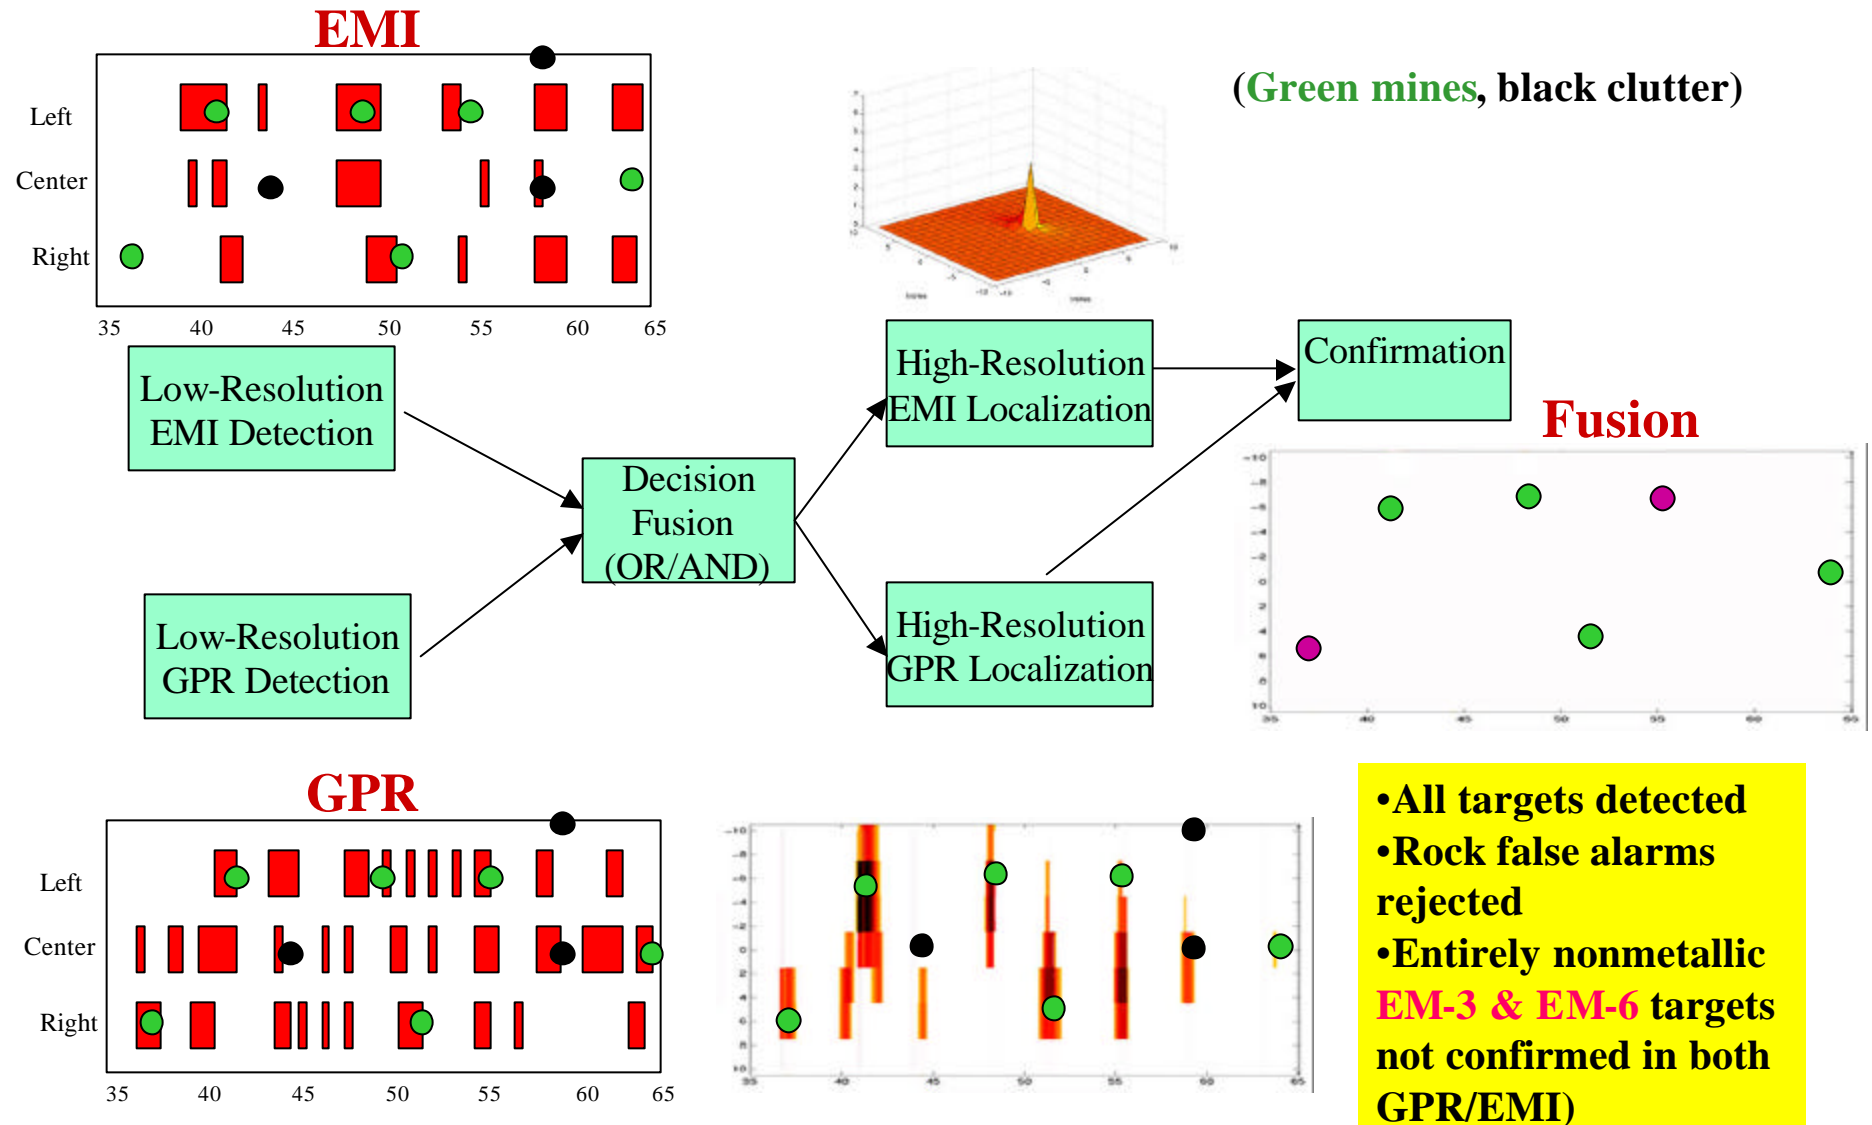

EMI: Accomplishments This Year

- Implemented and evaluated statistically based method for discriminate already detected-objects
- Algorithm characteristics
 - Based on analytical dipole scattering model
 - Able to process using time or frequency domain data
 - Capable of handling (and works best for) spatially sampled EM data
 - Inherently robust to modeling errors as well as uncertainty in position and orientation of the object
- Evaluated using
 - Synthetic data (time and frequency domain sensors)
 - Real GEM3 (frequency domain sensor)
 - Results encouraging
- Next up:
 - A min-max optimization approach for dealing with uncertainties in positioning of sensors

Multi-Frequency EMI Measurements: Mines and Clutter 5 cm deep - Background Removed Wet Sand (with Columbia University)

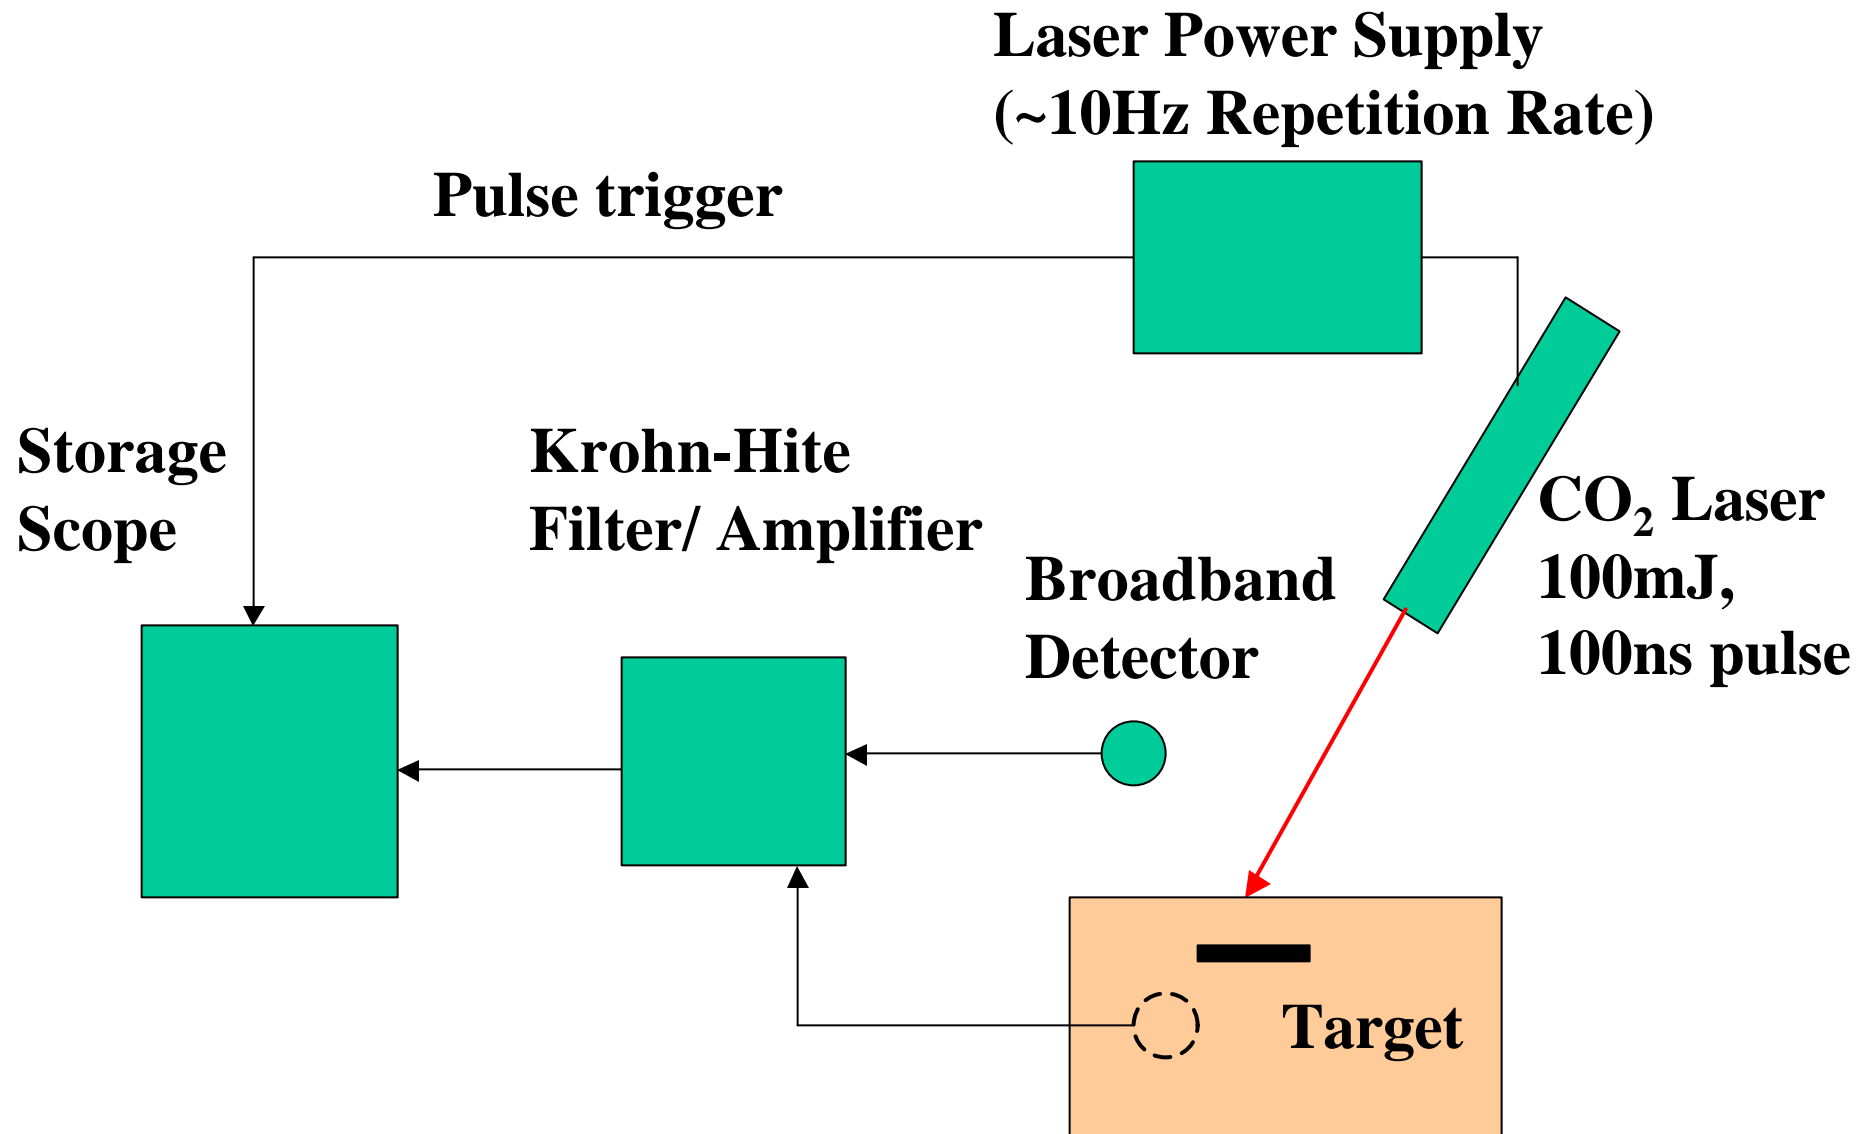

Multi-resolution Architecture for Clutter Rejection from GPR/EMI Fusion

Conclusion

NEU's Dedham Test Track provides an essential resource to enable the evaluation and verification of processing and fusion algorithms with real data from a well-characterized "ground truth" facility

Laser/Acoustic Experimentation

Broadband Detection of Laser-Induced Subsurface Scattering

Acoustic Array Buried Object Detection

Hydrophone
Array

Focused
CO₂ laser
beam

Hard rubber target
5cm x 2.5 cm thick

Overall Summary

- **Integrated Approach:** develop models, sensors, and algorithms in conjunction with each other for particular problem
- **New Sensors:** Multistatic Array GPR, Laser/Acoustic, MEIT, Microwave Probe, Artificial Dielectric Matching Layer
- **New Models:** Dispersive 3-D FDTD, Multi-object SDFMM, Sparse Preconditioned 3-D FDFD, Gaussian Beam Asymptotics
- **New Rough Surface Clutter Reduction Methods:** Time-Gated Frequency Response, Ground Clutter Pulse Capture and Removal
- **New Reconstruction:** Sequential Array Estimation, EMI Imaging, Multistatic Template Field Matching, Optimized F-K Migration

A Sliding Window RLS-like Adaptive Algorithm for Filtering alpha-stable Noise

Murat Belge and Eric L. Miller

Abstract— We introduce a sliding window adaptive RLS-like algorithm for filtering alpha-stable noise. Unlike previously introduced stochastic gradient type algorithms, the new adaptation algorithm minimizes the L_p norm of the error exactly in a sliding window of fixed size. Therefore, it behaves much like the RLS algorithm in terms of convergence speed and computational complexity compared to previously introduced stochastic gradient based algorithms which behave like the LMS algorithm. It is shown that the new algorithm achieves superior convergence rate at the expense of increased computational complexity.

I. INTRODUCTION

In the vast majority of signal processing applications it has been assumed that the signal or noise under investigation can be modeled by a Gaussian distribution law. This assumption has been justified by the central limit theorem and strong analytical properties of Gaussian pdf which leads to linear algorithms. However, in many real-world problems the noise encountered is more impulsive in nature than that predicted by a Gaussian distribution. Examples are underwater acoustic noise, low frequency atmospheric noise and many types of man-made noise [1]. Systems optimized under the Gaussian assumption often yield unacceptable performance when subjected to impulsive, non-Gaussian noise [12]. There exists a class of distributions, called alpha-stable distributions, than can be used to model these types of noise [1].

With the introduction of alpha-stable distributions to the signal processing community, a number of different adaptive filtering approaches have been proposed for filtering these processes [3], [5], [4], [7]. All of the algorithms that have been introduced so far can be classified as an LMS variant [8] which basically updates the filter coefficients by using an instantaneous approximation to the gradient of the cost function. The only difference of these algorithms from the conventional LMS algorithm is the minimization of the L_p norm of the error at the output of the adaptive filter instead of the usual Euclidean norm. The Least Mean p-Norm (LMP) algorithm [6] was derived exactly as described above. Later, motivated by the normalized versions of the LMS algorithm, Arikan *et. al.* developed the Normalized LMP (NLMP) algorithm [3]. Both LMP and NLMP suffer from the same problem that has plagued the LMS algorithm. Namely, when the input to the adaptive filter is highly correlated the convergence is very

slow. The RLO algorithm [7] is an alternative to LMP and NLMP, however its implementation requires some a-priori information on the error statistics and the filter inputs [7].

In this work, we develop a sliding window adaptation algorithm which is similar to the RLS algorithm [2] both in terms of derivation and convergence characteristics. The new algorithm provides much increased convergence rate at the expense of increased computational complexity. A block implementation of the new algorithm decreases the computational cost substantially.

II. SLIDING WINDOW LEAST MEAN P-NORM ADAPTATION ALGORITHM

The objective of an adaptation algorithm is to minimize the averaged error at the output of the filter by adjusting the coefficients of the filter. Adaptive estimation of a time-varying finite impulse response system is usually obtained by limiting the filtering memory. Here, we adopt a true finite memory or a sliding window approach for the adaptation of filter coefficients. That is we minimize the averaged L_p norm of the error in a window of size L :

$$J_{\underline{w}}(n) = \sum_{k=n-L+1}^n |d(k) - \underline{w}^t(n)\underline{x}(k)|^p = \sum_{k=n-L+1}^n |e(k)|^p \quad (1)$$

where $d(k)$ is the desired signal at time k , $\underline{w}(n)$ is the vector of optimal filter coefficients at time n , $\underline{x}(k) = [x(k) \ x(k-1) \dots x(k-N+1)]^t$ contains the N most recent samples of the input signal and $1 \leq p < 2$. Taking the gradient of $J_{\underline{w}}(n)$ with respect to $\underline{w}(n)$ and equating the result to zero we obtain:

$$\sum_{k=n-L+1}^n |e(k)|^{p-1} \text{sign}[e(k)] \underline{x}(k) = \underline{0} \quad (2)$$

which can be written as

$$\sum_{k=n-L+1}^n u(k) \underline{x}(k) \underline{x}^t(k) \underline{w}(n) = \sum_{k=n-L+1}^n u(k) d(k) \underline{x}(k) \quad (3)$$

where $u(k) = |e(k)|^{p-2}$, and (3) is obtained by substituting $\frac{e(k)}{|e(k)|}$ for $\text{sign}[e(k)]$ in (2) and rearranging. Defining $\underline{r}(n) = \sum_{k=n-L+1}^n u(k) d(k) \underline{x}(k)$ and $R(n) = \sum_{k=n-L+1}^n u(k) \underline{x}(k) \underline{x}^t(k)$ we obtain the following expression for $\underline{w}^*(n)$ which minimizes the p -norm of the error in a window of size L :

$$\underline{w}^*(n) = R^{-1}(n) \underline{r}(n) \quad (4)$$

Note, however, that $\underline{w}^*(n)$ cannot be readily obtained from (4) since $R(n)$ and $\underline{r}(n)$ are functions of $\underline{w}^*(n)$. However,

Dept. of Electrical and Computer Engineering, Northeastern University, Boston, MA 02148. This work was supported by an ODDR&E MURI under Air Force Office of Scientific Research contract F49620-96-1-0028, a CAREER Award from the National Science Foundation MIP-9623721, and the Army Research Office Demining MURI under Grant DAAG55-97-1-0013.

we can devise an iterative scheme to solve for $\underline{w}^*(n)$ at each point in time. Such an approach leads to the following algorithm:

Algorithm 1.

1. $\underline{w}^0(n) = \underline{w}^*(n-1)$
2. Compute $u^j(k) = |d(k) - \underline{x}^t(k)\underline{w}^j(n)|^{p-2}$, $k = n-L+1, \dots, n$
3. Compute $R^j(n) = \sum_{k=n-L+1}^n u^j(k)\underline{x}(k)\underline{x}^t(k)$ and $\underline{r}^j(n) = \sum_{k=n-L+1}^n u^j(k)d(k)\underline{x}(k)$
4. $\underline{w}^{j+1}(n) = [R^j(n)]^{-1} \underline{r}^j(n)$
5. If $\frac{\|\underline{w}^{j+1}(n) - \underline{w}^j(n)\|}{\|\underline{w}^j(n)\|} < \epsilon$ then, $\underline{w}^*(n) = \underline{w}^{j+1}(n)$, stop; else $j = j+1$, goto step 2

For each new input sample, we apply algorithm 1 to obtain the optimal filter coefficients, $\underline{w}^*(n)$, for the current time. Steps 2-5 of Algorithm 1 constitute the so-called *iterative re-weighted least squares* (IRLS) method which has been suggested and applied in several contexts [11], [9], [10]. The convergence of the IRLS algorithm can be guaranteed by making the following modification [9]:

$$u^j(k) = \begin{cases} u^j(k) & \text{if } u^j(k) \leq \frac{1}{\mu} \\ \frac{1}{\mu} & \text{if } u^j(k) > \frac{1}{\mu} \end{cases} \quad (5)$$

where μ is a small positive constant.

Note that, in step 4 of Algorithm 1, we need the inverse of $R^j(n)$. Rather than first computing $R^j(n)$ and then inverting this matrix to obtain $\underline{w}^{j+1}(n)$ we may consider computing $[R^j(n)]^{-1}$ directly in step 3 of Algorithm 1. To this end, consider the following expression for $i = L, \dots, 1$:

$$R^j(n-i+1) = R^j(n-i) + u^j(n-i+1)\underline{x}(n-i+1)\underline{x}^t(n-i+1) \quad (6)$$

Defining, $P^j(n) = [R^j(n)]^{-1}$, and applying the matrix inversion lemma [2] to (6) we obtain:

$$P^j(n-i+1) = P^j(n-i) - \frac{1}{\alpha(n-i)} \underline{g}(n-i) \underline{g}^t(n-i) \quad (7)$$

where $\underline{g}(n-i) = P^j(n-i)\underline{x}(n-i+1)$ and $\alpha(n-i) = 1/u^j(n-i+1) + \underline{x}^t(n-i+1)\underline{g}(n-i)$. Equation (7) implies that the matrix $P^j(n)$ can be obtained by a series of recursive updates starting from the matrix $P^j(n-L)$ at the beginning of the window. We assume that $P^j(n-L) = \frac{1}{\sigma}I$, which corresponds to a soft initialization [2]. Then, in step 4 of Algorithm 1, we compute $P^j(n)$ by using (7) instead of $R^j(n)$ and then obtain $\underline{w}^{j+1}(n)$ in step 5 by $\underline{w}^{j+1}(n) = P^j(n)\underline{r}^j(n)$.

The complexity of the algorithm given above is $O(MLN^2)$ where M is the number of IRLS iterations (steps 2-5 of Algorithm 1) needed. Because of the similarity of the algorithm to RLS, we call the new approach the recursive least mean p-norm algorithm (RLMP). The direct implementation of the RLMP algorithm is infeasible for most applications because of its high computational complexity which is dominated by construction of $P^j(n)$. However, a *subsampling* version of the RLMP algorithm where the filter coefficients are updated once at every k iterations, $k > 1$ being the subsampling rate, can be considered. In

Fig. 1. Transient behavior of tap weight adaptations for RLMP with $L = 50$, $k = 10$ (solid line), RLMP with $L = 100$, $k = 50$ (circles), NLMP (dashed line) and LMP (dash-dotted line) algorithms.

particular, if $k = L$, the complexity of the RLMP algorithm is $O(MN^2)$ per iteration. In this case, the filter coefficients are updated once for every data block of length L . As we will see in Section 3, the average number of IRLS iterations can be quite low making the subsampled version of the RLMP algorithm a viable alternative to its stochastic gradient type counterparts.

III. SIMULATION STUDY

In this section, we compare the performance of the RLMP algorithm to that of NLMP and LMP algorithms. In the NLMP and LMP algorithms, the coefficients of the adaptive filter is updated as follows [3]:

$$\underline{w}(n+1) = \underline{w}(n) + \alpha \frac{|e(n)|^{p-1} \text{sign}[e(n)]}{h(n)} \underline{x}(n) \quad (8)$$

where $h(n) = 1$ for LMP and $h(n) = \|\underline{x}(n)\|_p^p + \gamma$, with $\gamma > 0$ being a small constant, for the NLMP algorithm. Following [3], we consider the following AR process:

$$x(n) = 0.99x(n-1) - 0.1x(n-2) + u(n) \quad (9)$$

where $u(n)$ is an alpha-stable sequence of i.i.d. random variables with $\alpha = 1.2$, $\beta = 0$ and $\gamma = 1$. A simulation is performed to identify the coefficients of the AR process with the $p = 1.1$ norm. Figure 1 shows the transient behavior of the tap weights of the adaptive filter and Fig. 2 shows the norm of the error between the true and the estimated parameters, defined as $E(n) = 20 \log_{10} \|\underline{w}_{true} - \underline{w}(n)\|_2$. Both figures were obtained by averaging the results of 100 independent trials. The parameters of the RLMP algorithm are: $\mu = 10^{-6}$, $\sigma = 10^{-4}$, $\epsilon = 10^{-2}$. The RLMP algorithm was implemented for two different window sizes corresponding to $L = 50$ and $L = 100$ samples. For $L = 50$, the filter coefficients were updated once for every 10 iterations and for $L = 100$, the filter coefficients were updated once per 50 data samples. For a window of $L = 50$ samples, the RLMP algorithm produces a steady-state tap

Fig. 2. Transient behavior of tap weight error powers for RLMP with $L = 50$, $k = 10$ (solid line), RLMP with $L = 100$, $k = 50$ (circles), NLMP (dashed line) and LMP (dash-dotted line) algorithms.

weight error of approximately -20dB. This figure can be made smaller/larger by adjusting the window length. The step sizes of the NLMP and the LMP algorithms were set to produce the same steady state tap weight error as RLMP. The step size for NLMP was found to be 3.8×10^{-2} and 5×10^{-5} for LMP. Figure 1 and 2 show that RLMP provides a large improvement in convergence rate over the NLMP and LMP. To give an idea about the number of iterations needed for the outer IRLS iterations to converge, we computed the number of IRLS iterations at each discrete time, n , by averaging 100 trials. The results are displayed in Fig. 3. It is seen that at most 3 iterations are sufficient to obtain a relative error $\frac{\|w^{j+1}(n) - w^j(n)\|}{\|w^j(n)\|}$ of about 10^{-2} .

Examining Algorithm 1 in detail, we see that the most efficient implementation of the RLMP algorithm requires $ML(2N^2 + 3N + 2)$ multiplications, $2ML$ divisions and ML nonlinear operations per update of the filter coefficients. In general, for $k = L$ (i.e. filter coefficients are updated once for each data block of L samples), the computational effort required by the RLMP algorithm is approximately M times that of a single RLS update plus M nonlinear operations. From Fig. 3, we see that, for this example, the ensemble average of M is actually quite low and approximately 2.5 at the steady state.

IV. CONCLUSION

In this letter, we described a novel adaptation algorithm for filtering alpha-stable noise. The new algorithm is derived by minimizing the averaged L_p error at the output of the filter in a window of fixed size. Simulations show that the new algorithm provides much improved convergence rate compared to other stochastic gradient based adaptation algorithms for alpha-stable noise environments. The major disadvantage of the algorithm is its computational complexity. We proposed a subsampled implementation of the RLMP algorithm which reduces the computational complexity to $O(MN^2)$ per data sample. Current

research is focused on frequency domain implementations of the RLMP algorithm which will further reduce the computational complexity.

Abstract

The problem of characterizing the structure of an object buried in an inhomogeneous half-space of unknown composition is considered. We develop a non-linear inverse scattering algorithm based on a low dimensional parameterization of the unknown object and the background. In particular, we use low order polynomials to represent the contrast in the real and imaginary parts of the object and background complex permittivities. The boundary separating the target from the unknown background is described using a periodic, quadratic B-spline curve whose control points can be individually manipulated. We determine the unknown control point locations and contrast expansion coefficients using a greedy-type approach to minimize a regularized least-squares cost function. The regularizer used here is designed to constrain the geometric structure of the boundary of the object and is closely related to snake methods employed in the image processing community. We demonstrate the performance of our approach via extensive numerical simulation involving 2D, TM_z scattering geometries.

1 Introduction

We consider the problem of localizing and characterizing the structure of an object buried in a halfspace given noisy observations of scattered electromagnetic fields collected near the interface. Such problems arise in application areas including environmental remediation, humanitarian demining, medical imaging and non-destructive testing [6, 11, 14, 26]. Here we are particularly concerned with addressing two of the many challenges associated with such inverse scattering problems. First, these problems are known to be highly ill-posed in that the quantity of information contained in the data, which are collected only near the interface, is quite limited relative to the amount of information one would like to extract. This leads to considerable instabilities in terms of reliably characterizing the behavior of the subsurface [21, 25]. A second difficulty is the need to deal with *clutter*. Here we take clutter to be physical characteristics of the medium, in particular volume inhomogeneities, whose presence impedes our ability to characterize the object of interest.

Typical methods for overcoming these two problems are based on forming an image of the subsurface and then post processing the results to extract target information [5, 27]. The issue of ill-posedness is addressed through the use of a regularization procedure [3, 23, 25] to stabilize the imaging portion of the algorithm while clutter suppression is achieved through the use of image processing methods to separate targets from background. In forming an image, however, one must solve a large scale, non-linear optimization problem whose size is equal to the number of pixels (voxels) in the region of interest; a highly computationally intensive process. Moreover, under this approach one uses the limited data to generate values for all of the pixels only a few of which contain useful information about the underlying target. By diffusing the information in the data in this manner, target detection can be problematic [24].

There has been considerable work in the past decade on methods that extract directly from the data geometric information regarding the shape and location of the object [8–13, 19, 21, 22, 29, 32].

The assumption underlying most of these methods is that the object is embedded in a medium of otherwise known structure (homogeneous or halfspace). Rather than parameterizing the problem in terms of a large number of pixel values, a relatively small number of unknowns are used to describe the shape of the target. For these methods the issue of ill-posedness is either addressed through a regularization procedure related to the shape of the object [21] or through the use of more traditional Tikhonov or minimum norm least squares methods [11, 15, 32].

For our problems, these shape-based methods are not applicable. For example, the approach taken in [13] requires that the object be surrounded on all sides by transmitters and receivers. While this assumption is satisfied in, for example, medical imaging applications, we are restricted here to problems where we have only reflection-type data at our disposal. Additionally, most of the previously developed techniques assume that the electrical properties of the background are fully known and in many cases, the object's contrast function is also specified *a priori* [22]. Because we wish to address the issue of volume inhomogeneity, we must look to a different approach.

Hence we consider a parameterization based on a concise description of the object's geometric structure that provides for the recovery of a limited amount of information regarding the spatial variations of the complex permittivity over the target and the background. As described in § 2, the variations in the background and the object contrast are modeled via a superposition of a small number of expansion functions; one set of functions for the background and separate set for the object. Thus, the unknowns here are the corresponding expansion coefficients.

As in [1, 11, 21], we seek a representation for the shape of the object in terms of a small number of unknowns. In previous work, a Fourier-type expansion is used in conjunction with an underlying assumption that the object of interest is star-like. Here we choose to describe the boundary of the objects differently, using a linear combination of quadratic B-splines [4, Chap. 3]. The motivation for this choice comes from the fact that the parameters governing this representation (known as

control points) impact the shape of the object only over a small portion of the perimeter. Thus, the control points provide direct and local control over the object's shape. This control is exploited in the development of a simple and efficient inversion scheme described in § 3. Finally, the control-point parameterization leads to a natural, shape-based regularization technique related to *snake* methods [4] used in image processing for contour representation and image segmentation.

We view this approach as a compromise between an ill-posed imaging method that allows for arbitrary variation throughout the region and the more constrained shape-based methods in which homogeneity is assumed. By restricting the contrast variations to lie within the linear span of a set of basis functions, we clearly limit the classes of variations which can be recovered from this inversion process. The motivation for this decision comes from the fact that a detailed reconstruction of the medium is often not what is desired nor is it supported by the information in the data. Rather, the primary information of interest concerns the geometric structure of the object. Thus we are willing to settle for a coarse reconstruction of the object and background contrast functions.

The remainder of this paper is arranged as follows. In § 2, the scattering problem and the models for the object and background are presented; § 3 gives a presentation of the inversion procedure with examples of its performance shown in § 4. Conclusions and future work are described in § 5.

2 Problem formulation

We consider a two-dimensional scattering problem illustrated in Fig. 1. Time harmonic $e^{-j\omega t}$ y -polarized plane waves at various incident angles and frequencies are used to probe the medium. The complex permittivity of the lower halfspace is represented as the sum of a nominal, constant value, $\epsilon_1 + (j/\omega)\sigma_1$, and a space varying perturbation,

$$g(\mathbf{r}) = \epsilon_0 \epsilon_p(\mathbf{r}) + \frac{j}{\omega} \sigma_p(\mathbf{r}), \quad (j = \sqrt{-1}), \quad (1)$$

that encompasses both the object of interest as well as the clutter. Here, $\mathbf{r} = [x \ z]^T$ is a two vector indicating the position of a point in the plane, ϵ_0 is a constant that denotes the permittivity of free space, and ω denotes angular frequency. The scattered fields generated by g are observed along an array of point receivers also located in the upper halfspace. Under this 2D model, there is only a single component of the electric field thereby resulting in a scalar scattering problem.

The model linking the structure of g to the observed scattered field at the k th point along the array, \mathbf{r}_k , is [7, Chap. 9]

$$y(\mathbf{r}_k) = \omega^2 \mu_0 \int_W G(\mathbf{r}_k, \mathbf{r}') E(\mathbf{r}') g(\mathbf{r}') d\mathbf{r}' + n(\mathbf{r}_k), \quad (2)$$

where $y(\mathbf{r}_k)$ is the datum at \mathbf{r}_k for a given incident field, W is the region over which g is nonzero, n is zero mean, additive white Gaussian measurement noise with variance ζ^2 , and G and E denote the Green's function and total electric field, respectively. The constant μ_0 denotes the permeability of free space. In (2), we are only concerned with evaluating the Green's function, $G(\mathbf{r}, \mathbf{r}')$, when \mathbf{r} is above the interface and \mathbf{r}' is below in which case [10]

$$G(\mathbf{r}, \mathbf{r}') = \frac{j}{2\pi} \int_{-\infty}^{\infty} \frac{1}{\gamma_0 + \gamma_1} \exp [j\alpha(x - x') + j(\gamma_1 z - \gamma_0 z')] d\alpha \quad (3)$$

with $\gamma_i = (k_i^2 - \alpha)^{1/2}$ where $k_i = \omega \sqrt{\epsilon_i \mu_0 + j\sigma_i \mu_0 / \omega}$ denotes the wavenumber in the upper ($i = 0$) and lower ($i = 1$) halfspace. The total electric field $E(\mathbf{r})$ is governed by the Helmholtz equation

$$[\nabla^2 + k^2(\mathbf{r})] E = 0$$

with a Sommerfeld radiation condition where $k^2(\mathbf{r})$ is equal to k_0^2 above the interface and $k_1^2 + \omega^2 \mu_0 g(\mathbf{r})$ below. Finally, the total electric field at \mathbf{r} is the sum of the unperturbed electric field generated by a plane wave impinging on a halfspace, $E_{unp}(\mathbf{r})$, [20, § 3.2] and the scattered electric field, $E_s(\mathbf{r})$. With $E = E_s + E_{unp}$, it is easy to show that:

$$[\nabla^2 + k^2(\mathbf{r})] E_s = -\omega^2 \mu_0 g(\mathbf{r}) E_{unp}. \quad (4)$$

As $y(\mathbf{r})$, the observed field, depends on the total field in the region W , it therefore implicitly depends on the particular unperturbed field, E_{unp} , on $g(\mathbf{r})$, and on the frequency ω .

2.1 A Model for $g(\mathbf{r})$

As described in the introduction, we model the unknown portion of the permittivity in the lower halfspace as a superposition of a slowly varying, compactly supported anomaly (the target) on a background of partially known structure (clutter). Mathematically $\epsilon_p(\mathbf{r})$ is decomposed as

$$\epsilon_p(\mathbf{r}) = S(\mathbf{r}) \sum_{i=1}^{N_a} a_{1,i} b_{1,i}(\mathbf{r}) + [1 - S(\mathbf{r})] \sum_{i=1}^{N_b} a_{2,i} b_{2,i}(\mathbf{r}) \equiv S(\mathbf{r}) B_1(\mathbf{r}) \mathbf{a}_1 + [1 - S(\mathbf{r})] B_2(\mathbf{r}) \mathbf{a}_2 \quad (5)$$

where $S(\mathbf{r})$ is one over the (unknown) support of the object and zero elsewhere. The functions $b_{1,i}$ represent basis functions describing the contrast of the real part of the anomaly while the $b_{2,i}$ do the same but for the background. The $a_{i,j}$ are the expansion coefficients determining the weight of each function. The row vectors B_i , $i = 1, 2$ hold the expansion functions and \mathbf{a}_i are vectors of expansion coefficients. An analogous model holds for $\sigma_p(\mathbf{r})$, which is proportional to the imaginary portion of $g(\mathbf{r})$:

$$\sigma_p(\mathbf{r}) \equiv S(\mathbf{r}) B_1(\mathbf{r}) \mathbf{c}_1 + [1 - S(\mathbf{r})] B_2(\mathbf{r}) \mathbf{c}_2. \quad (6)$$

While in principle the expansion functions could differ between ϵ_p and σ_p , the support function S is the same since it represents a physical boundary between the object and the rest of the medium.

The particular choice of the $b_{i,j}$ depends on the application at hand. If one thought that there was a homogeneous dielectric anomaly of contrast $a_{1,1}$ against a real-valued homogeneous background of value $a_{2,1}$ then one would take $b_{1,1}(\mathbf{r}) = b_{2,1}(\mathbf{r}) = 1$. Use of higher order polynomials, trigonometric functions etc. provide greater flexibility in capturing true, underlying inhomogeneities. In any event, assuming the B_i are known, the objective of the problem in this paper is to determine the structure of S along with the \mathbf{a}_i and \mathbf{c}_i given the observed scattered field data.

In this work, we employ a B-spline model to describe the contour of the anomaly, that is, the boundary of the set $S(\mathbf{r})$. To define this curve, we start with an interval $[0, L]$ on which a *knot* sequence k_0, \dots, k_{K-1} with $0 \leq k_i \leq L$ is defined. For this sequence, there exists a periodic basis

of quadratic B-splines $C_{k_i}(s)$ such that

$$b(s) \equiv [x(s), z(s)] = \sum_{i=0}^{K-1} C_{k_i}(s)[x_i, z_i], \quad s \in [0, L] \quad (7)$$

for a given set of x_i, z_i expansion coefficients, or *control points*, uniquely defines a closed, C^2 parametric curve in the plane. The support of each $C_{k_i}(s)$ is $[k_i, k_{i+3}]$. Since the basis is taken to be periodic, the control points are assumed to be wrapped; that is, $[x_0, z_0] = [x_{K-2}, z_{K-2}]$ and $[x_1, z_1] = [x_{K-1}, z_{K-1}]$, so there are a total of K control points, $K - 2$ of which are unique.

To implement our model, we assume that the boundary of the anomaly is in the form:

$$b^*(s) \equiv \sum_{i=0}^{K-1} C_{k_i}(s)[x_i^*, z_i^*]. \quad (8)$$

If $\mathbf{r} = [x \ z]^T$ is a point inside $b^*(s)$, then for example, $\epsilon_p(\mathbf{r})$ is $B_1(\mathbf{r})\mathbf{a}_1$, while for \mathbf{r} outside, $\epsilon_p(\mathbf{r}) = B_2(\mathbf{r})\mathbf{a}_2$.

3 Algorithm

In this section we describe in detail the algorithm we use to solve the inverse problem. We begin by discussing the discretized form of the model. The reader is referred to Table 1 for a summary of the indexing parameters that have been or will be identified.

3.1 Discretization

Using the method of moments [17] with a pulse basis and point matching to discretize (2) and a lexicographical ordering of the unknowns yields the matrix equation:

$$\mathbf{y} = \mathbf{G}\mathcal{D}(\mathbf{E})\mathbf{g} + \mathbf{n}, \quad \mathbf{y} \in C^{M \times 1} \quad (9)$$

where M is the number of source/receiver pairs, \mathbf{y} and \mathbf{n} are vectors with components $y(\mathbf{r}_k)$ and $n(\mathbf{r}_k)$ respectively, \mathbf{G} the discrete Green's function premultiplied by $\omega^2\mu_0$, $\mathcal{D}(\cdot)$ is the diagonal matrix formed from the vector argument, and \mathbf{E} is the vector containing the total electric field (which depends on \mathbf{g}) at each pixel. Finally, $\mathbf{g} \in C^{N \times 1}$ is a vector holding the intensity values of

$g(\mathbf{r})$ at the N grid points in our discretization of the subsurface and from (5) and (6) is given as:

$$\mathbf{g} = \epsilon_0[\mathbf{S}\mathbf{B}_1 - (\mathbf{I} - \mathbf{S})\mathbf{B}_2]\mathbf{a} + \frac{j}{\omega}[\mathbf{S}\mathbf{B}_1 - (\mathbf{I} - \mathbf{S})\mathbf{B}_2]\mathbf{c} \equiv \left[\epsilon_0\mathbf{V} \quad \frac{j}{\omega}\mathbf{V} \right] \mathbf{w} \quad (10)$$

where $\mathbf{a} = [\mathbf{a}_1^T \quad \mathbf{a}_2^T]^T$, $\mathbf{c} = [\mathbf{c}_1^T \quad \mathbf{c}_2^T]^T$, $\mathbf{w} = [\mathbf{a}^T \quad \mathbf{c}^T]^T$, \mathbf{S} is a diagonal matrix corresponding to S with $\mathbf{S}_{i,i} = 1$ if any part of pixel i is inside $b^*(r)$ and 0 otherwise, \mathbf{I} is the identity matrix, and the \mathbf{B}_i denote the $N \times N_a$ and $N \times N_b$ matrices corresponding to evaluating $B_i(r)$ at the N gridpoints.

Finally, using $\mathbf{A} = \mathbf{G}\mathcal{D}(\mathbf{E})$ with (10) and (9) we have

$$\mathbf{y} = [\epsilon_0\mathbf{A}\mathbf{V}, \quad \frac{j}{\omega}\mathbf{A}\mathbf{V}]\mathbf{w} + \mathbf{n} \equiv \mathbf{K}\mathbf{w} + \mathbf{n}, \quad \mathbf{y} \in C^{M \times 1}. \quad (11)$$

Note that there is one such matrix-vector equation of this form for each frequency and each different incident angle. In the remainder of the paper, we assume n_1 frequencies and n_2 angles are used, and we use double superscripts i, k to denote the corresponding vectors and matrices at frequency ω_i and angle θ_k : single superscripts imply that that quantity depends only on ω_i . For example, $\mathbf{y}^{i,k}$ denotes the data obtained via (9) or (11) for frequency ω_i and incident angle θ_k

$$\mathbf{y}^{i,k} = \mathbf{G}^i \mathcal{D}(\mathbf{E}^{i,k}) \mathbf{g}^i + \mathbf{n}^{i,k} = \mathbf{K}^{i,k} \mathbf{w} + \mathbf{n}^{i,k}, \quad (12)$$

whereas \mathbf{g}^i denotes (10) at frequency ω_i .

3.2 Generating Scattered Field

To generate the data for a given frequency ω_i and incident angle θ_j , we need to compute the M -length vector $\mathbf{E}^{i,j}$ (i.e. we need to solve the forward scattering problem). To do this, we determine the scattered field by discretizing (4) using a finite difference scheme with PML boundary condition (details are described in [18]) to obtain the matrix equation $\mathbf{M}^i \mathbf{E}_s^{i,j} = -\omega_i^2 \mu_0 \mathbf{g}^i \mathbf{E}_{unp}^{i,j}$ where the unperturbed field $\mathbf{E}_{unp}^{i,k}$ is known and depends on incident angle and frequency, and \mathbf{M}^i is the matrix corresponding to the discretized operator in (4) with the PML boundary condition. The scattered field is determined by solving the matrix equation for $\mathbf{E}_s^{i,j}$, and finally, $\mathbf{E}^{i,j} = \mathbf{E}_{unp}^{i,j} + \mathbf{E}_s^{i,j}$.

3.3 Algorithm Description

Our algorithm seeks to find a good approximation to $g(\mathbf{r})$ by successively generating better and better approximations to $b^*(s)$, the boundary of the anomaly, and the coefficient vectors \mathbf{a} and \mathbf{c} .

In particular, we seek a minimum of the following cost function

$$J(b(s), \mathbf{a}, \mathbf{c}) = \sum_{i=1}^{n_1} \sum_{k=1}^{n_2} \|\mathbf{y}^{i,k} - \mathbf{G}^i \mathcal{D}(\mathbf{E}^{i,k}) \mathbf{g}^i\|_2^2 + \lambda_1 \Omega_1(b(s)) + \lambda_2 \Omega_2(b(s)). \quad (13)$$

where we emphasize that both $\mathbf{E}^{i,j}$ as well as \mathbf{g}^i depend implicitly on the geometry of the anomaly as well as the expansion vectors via the models developed in § 2 and § 3.1. The first term in (13) enforces fidelity to the data while the second and third play the role of regularizers.

Traditional regularization methods used to combat ill-posedness in an image restoration framework function by enforcing smoothness, or in some cases edge preservation, in the reconstruction. In our case, the $\Omega_i, i = 1, 2$ are used to influence the geometric structure of the recovered anomaly. Specifically, we define these functions as

$$\Omega_1(b(s)) = \sum_{i=0}^{K-2} (z_i - z^*)^2 \quad \text{and} \quad \Omega_2(b(s)) = \sum_{i=0}^{K-2} (x_i - x_{i+1})^2 + (z_i - z_{i+1})^2 \quad (14)$$

where K is the total number of control points, x_i and z_i are the coordinates of the i th control point, and z^* is a fixed z -value depending on the particular application. The first term attempts to penalize objects that are too deep while the second penalizes the total length between control points. In this way we dissuade the algorithm from choosing curves that are overly elongated and/or deep. Our justification for the first of these choices comes from our knowledge that significant depth information is not available in the measured data due to the loss in the soil and the positioning of detectors only above the interface. Moreover, in most applications one possesses some *a priori* information concerning the depth at which targets are likely to be buried. The values of λ_1, λ_2 tell how strongly we want to dissuade the algorithm from reconstruction of curves that are too elongated and/or deep. Finding near optimal regularization parameters is a very difficult problem and there is a whole body of literature dedicated to this issue (see, for instance, [2, 16]). In this work, we assume

that good parameters are known *a priori*: determining accurate parameter selection strategies will be the subject of future work.

We consider a greedy-type algorithm for minimizing (13). We begin with an initial estimate, $b^{(0)}(s)$, of $b^*(s)$ defined by a set of K knots and $K - 2$ distinct control points. From $b^{(0)}(s)$ the matrix \mathbf{S} is found. Suppose for the moment that initial estimates of \mathbf{a}, \mathbf{c} , denoted $\mathbf{a}^{(0)}, \mathbf{c}^{(0)}$, are known (we address the issue of generating these guesses below). Using (10), the \mathbf{g}^i are calculated for the different frequencies. We then use (13) to determine the cost of $(b^{(0)}, \mathbf{a}^{(0)}, \mathbf{c}^{(0)})$.

We update the estimate of $b^{(0)}(s)$ by systematically perturbing each control point from its original position by a fixed amount \bar{h} in the horizontal, vertical, and diagonal directions, respectively, for a total of 8 different moves per point. Note that each of these 8 moves corresponds to a new curve by definition in (7). Since there are $K - 2$ unique points and 8 moves for each point, this corresponds to $8(K - 2)$ different possible new curves. For each possible curve, we first estimate new values for \mathbf{a} and \mathbf{c} and then evaluate the cost associated with the current curve and these estimates using (13). Finally, $b^{(1)}(s)$, $\mathbf{a}^{(1)}$, and $\mathbf{c}^{(1)}$, our new estimates, are taken as that triple giving minimum cost, provided that cost is less than (or equal to) the cost associated with $(b^{(0)}(s), \mathbf{a}^{(0)}, \mathbf{c}^{(0)})$. The process is repeated as many times as is necessary.

In principle, determination of \mathbf{a} and \mathbf{c} requires the solution of a low dimensional inverse scattering problem. That is, every time we want to determine the cost for a candidate curve, we need to solve a non-linear optimization problem. To simplify this procedure, we consider an alternative approach. At the end of the k th stage, we compute the internal fields associated with the current estimate of the anomaly. This requires the solution of $n_1 n_2$ forward scattering problems of size N . From (9), the data $\mathbf{y}^{i,l}$ depend on the anomaly through \mathbf{g}^i and the internal fields. At stage $k + 1$, we assume that as we move the control points to generate new candidate structures, the changes in the internal fields are negligible compared to the changes in the \mathbf{g}^i . Thus, for each of these candidates,

we hold the internal fields fixed at the values computed at the end of the previous stage.

This approach is useful for two reasons. First, it reduces the number of forward solves associated with each iteration from $8(K-2)n_1n_2$ to just n_1n_2 . Second, by holding the internal fields fixed, (9) and (11) indicate that the unknown expansion coefficients are locally *linearly* related to the data. Thus, estimates of these quantities can be obtained via a linear least squares procedure that is far less demanding than a nonlinear optimization problem. In particular, we have

$$\hat{\mathbf{w}} = \arg \min_{\mathbf{w}} \|\mathbf{K}\mathbf{w} - \mathbf{y}\|_2^2 = (\mathbf{K}^T\mathbf{K})^{-1}\mathbf{K}^T\mathbf{y} \quad (15)$$

where \mathbf{K} is the matrix obtained by stacking all of the real and imaginary parts of $\mathbf{K}^{i,k}$ defined in (11) and (12) and (with a slight abuse of notation) \mathbf{y} is the corresponding stacked real and imaginary parts of $\mathbf{y}^{i,k}$.

Now we address the choice of $\mathbf{a}^{(0)}, \mathbf{c}^{(0)}$. Solving (15) requires \mathbf{K} , which by (11) requires $\mathbf{A}^{i,k}$, which in turn requires $\mathbf{E}^{i,k}$. But computing $\mathbf{E}^{i,k}$ according to §3.2 would require prior knowledge of the unknown \mathbf{g}^i . Thus, to get initial estimates of the expansion coefficients, we set $\mathbf{E}^{i,k}$ to $\mathbf{E}_{unp}^{i,k}$; in other words, we use the Born approximation to determine initial guesses of $\mathbf{a}^{(0)}, \mathbf{c}^{(0)}$.

The algorithm is initialized using an object of size larger than any target of interest located in the vicinity of the true object. There are many possible methods for determining such an initial guess. For example, there are methods that determine a “best fit” disk as an initialization: one based on array processing is described in [28] while another based on statistical hypothesis testing is detailed in [24]. Here, we always assume that the initial object is given and refer the reader to the literature for specific techniques to determine this guess.

The overall algorithm is sketched in Fig. 2. One advantage of this approach is that it is quite easy to implement and in principle, all candidates at any given stage can be generated in parallel. Thus it is computationally attractive. It is not difficult to prove that if we were to recompute the internal fields for each possible control point move (rather than leaving it fixed at the previous

estimate), then we would be guaranteed that at every outer iteration of our algorithm the cost would be non-increasing. By insuring old curves cannot be regenerated¹, this would imply convergence of the algorithm to a minimum of (13) taken over the collection of anomalies that can be generated by these moves. However, since we hold the internal fields fixed as we loop over control point moves and update them only after a move is chosen, monotonicity of the cost cannot be guaranteed. Generally, we have noticed through extensive simulation that as long as the parameters λ_1 and λ_2 are well chosen, the cost does in fact decrease as the iterations progress.

4 Numerical Examples

In this section we present several numerical examples that illustrate the effectiveness of our algorithm. All experiments were done in Matlab using double precision arithmetic. Creation and manipulation of the B-spline curves was achieved with Matlab's Spline Toolbox.

In all of the numerical examples, we used three frequencies (500, 700, and 900 MHz) and three incident angles ($0, \pi/4, -\pi/4$). The region of interest for which we would like to obtain an image was 40cm across (-20cm to 20cm) and 20 cm deep (0 to 20cm). We discretized this region into pixels of size 1cm-by-1cm. Data were collected at 19 receivers located at -18cm to 18cm in 2cm increments. To define the entries of the Green's function matrix G , we set $\epsilon_1 = 2.5\epsilon_0, \sigma_1 = 3E - 3$, which corresponds to assuming that the upper halfspace is air and the lower halfspace is sand. Depending on the example, we fill the $B_i(\mathbf{r})$ matrices of (5) and (6) with monomials of at most degree 2. Finally, Table 2 summarizes the parameters for each of the experiments. The values for the λ_i were chosen by trial and error. In all experiments, the value of the step size, \bar{h} , was taken to be one centimeter. Finally, the contours of all the true objects were generated using a B-spline with $K = 6$ knots while the reconstructions were generated for a $K = 5$ knot contour.

¹It turns out that our approach to updating the internal electric field can create the situation in which distinct curves yield the same cost. Thus we implement extra logic in our implementation to ensure that we never enter a loop.

To produce noisy data, independent additive Gaussian noise was added to both the real and imaginary parts of the noise free data. Letting $\tilde{\mathbf{y}}$ denote the vector obtained by stacking $\mathbf{K}^{i,j}\mathbf{w}$ for all frequencies and incident angles we have $\mathbf{y} = \tilde{\mathbf{y}} + \mathbf{n}$ where $\mathbf{n} = \zeta_r \mathbf{n}_r + j\zeta_i \mathbf{n}_i$ and $\mathbf{n}_r, \mathbf{n}_i$ were generated using Matlab's `randn` function. The constants ζ_r, ζ_i were determined so that the signal-to-noise ratio (SNR) with respect to the real and imaginary parts of $\tilde{\mathbf{y}}$ were the same:

$$SNR = 10 \log_{10} \frac{\text{real}(\tilde{\mathbf{y}})^T \text{real}(\tilde{\mathbf{y}})}{\zeta_r N} = 10 \log_{10} \frac{\text{imag}(\tilde{\mathbf{y}})^T \text{imag}(\tilde{\mathbf{y}})}{\zeta_i N}.$$

We used two measures of success in comparing our reconstructions with the true images. The first is a relative error measure over all pixels in the union of the true curve and the reconstructed curve, which we index by the index set \mathcal{I} :

$$SE = \frac{\|\epsilon_{true}(\mathcal{I}) - \epsilon_p(\mathcal{I})\|^2}{\|\epsilon_{true}(\mathcal{I})\|^2} + \frac{\|\sigma_{true}(\mathcal{I}) - \sigma_p(\mathcal{I})\|^2}{\|\sigma_{true}(\mathcal{I})\|^2}$$

For each example, we also recorded the maximum pointwise relative error in the real (imaginary) part of the solution over the pixels in the intersection of the true and reconstructed curves. The values for these measures for the 5 examples described below are in Table 4.

4.1 Examples 1 and 2: Homogeneous Perturbations

As a first example, we consider the problem with a homogeneous object of unknown contrast embedded in a homogeneous half-space at an SNR of 20 dB, Fig. 3(a)–(b). While the inversion scheme knows the correct basis function to use for the object and background (i.e. $N_a = 1 = N_b$ in (5) and (6) with $b_{1,1} = 1 = b_{2,2}$ in both cases) it still does not know the values of the expansion coefficients. In Fig. 3(e) we display the true boundary of the object along with the initial guess of this quantity and the final boundary estimate produced by our algorithm. The true and estimated images of the ϵ_p and σ_p for this problem are shown in Fig. 3(c)–(d) where we observe that the unknown contrasts are estimated quite accurately. This conclusion is supported by the numerical values for our figures of merit given in Table 4.

For comparison sake, we have also implemented a more traditional Born iterative method (BIM)

[31] inversion procedure using a TSVD (truncated singular value decomposition) regularization technique to stabilize the linear system that must be solved at each iteration. After optimizing the regularization parameter for this procedure, the reconstructions of the real and imaginary parts of \mathbf{g} are shown in Figs. 4.

This example demonstrates that even under noisy circumstances, the approach we have proposed is able to capture accurately both the shape and the numerical values of the unknown permittivity and conductivity of the object. While the BIM clearly indicates the presence of an object in ϵ_p , almost nothing is seen in the σ_p image. Further, note that the anomaly boundary is much less well reconstructed compared to our new approach. Also, numerous artifacts appear in both parts of the reconstruction. By constraining the reconstruction as is done in our algorithm, we obtain a much more accurate representation of the true profile. Our reconstructed object differs from the true by only four pixels. Moreover, the amplitudes of ϵ_p and σ_p are quite close to their true values.

The performance of our approach is further verified in Fig. 5 where we display boundary curves and true and estimated images of ϵ_p and σ_p for an object rotated relative to the interface. The BIM plots are shown in Fig. 6. The same level of performance as was seen in the previous example is also seen here. Moreover, because we reconstruct the boundary explicitly, this approach allows us to easily characterize the orientation of the buried object, a potentially useful piece of information for later processing stages concerned with identification and classification.

4.2 Cramer-Rao Bounds for Examples 1 and 2

We next turn our attention to more challenging problems in which the electrical properties of both the background and the object can vary. A first issue of concern is construction of the B matrices used to model these variations. Intuitively, we expect that that as the size of the object falls, it will be increasingly difficult to recover higher order information about the target structure when the profile of the much larger background region is also unknown. In fact, we can quantify

the validity of this idea using the notion of a Cramer-Rao bound (CRB).

As explained more fully in [30, § 2.4], the CRB provides a lower bound on the variance of any unbiased parameter estimator in a noisy data information extraction procedure of the type considered here. The CRB is a deterministic quantity reflecting the nature of the physical model, the parameterization of the problem, and statistics of the noise corrupting the data. While we make no claims here concerning the bias of our estimator, the CRB provides a useful gauge as to the maximum confidence we should have in the numerical values of the \mathbf{a} and \mathbf{c} estimates produced by our algorithm. Specifically, by examining the bounds for different configurations of object and background, we obtain insight into how we may want to structure our inversion algorithm.

Here we consider our ability to recover information concerning at most linear variations in both the background and the object, i.e. cases in which the real or imaginary parts of these quantities behave as $d_0 + d_1x + d_2z$ where the d_j can represent any of the $a_{i,j}$ or $c_{i,j}$ coefficients appearing in the model of § 2.1. This level of complexity is sufficient to understand the basic issues. In particular, we consider CRB information for objects of three sizes with linear contrast variations (shown in Fig. 7) embedded in backgrounds whose variations are also linear. Fig. 8 illustrates the configurations of interest for the medium size object. The SNR for all experiments is 30 dB.

The numerical values of the square roots of the CRBs (i.e. the lower bounds on the standard deviations) for the experiments are provided in Table 3. The first column refers to the coefficient in the model. For example, the row beginning “Object real: const.” holds the information regarding the true value and the bound on the constant coefficient in the real part of the object. Similarly, “Bkgnd real: x ” is the row for the coefficient governing the real part of the x variation in the background. In all cases, the bounds on the coefficients governing the background are a small fraction of the true values and vary little with the size of the embedded object. These small bounds imply small variance in the estimates of the background structure and thus indicate that we can

in fact determine these quantities rather accurately. This is true both for the constant term in the variation as well as the linear terms. In contrast, our ability to recover anything but the unknown constant term describing the object is more limited. The bounds on the x and z coefficients are at best on the order of the true values and grow at a much more rapid rate as the object size decreases making determination of these quantities a very delicate procedure.

With this in mind, in the remainder of this paper (with the exception of Example 5) we consider object models comprised of only unknown constants. As we show below, even when the true object is of a more complex structure, the use of this simple model still allows for accurate localization and the recovery of limited quantitative information. In light of the underlying objective of our approach, we view this tradeoff of accuracy in “pixel” space for accuracy in localization and geometric characterization as acceptable. In terms of specifying the model for the background, the situation is less clear. Extensive numerical experiments (not reported here) indicate that one needs a relatively accurate model to achieve good localization. That is, the order of the model should approximate well the true distribution of the volume inhomogeneity. As a rigorous solution to the model order determination problem is outside of the scope of this paper, here we consider only models whose order meets or exceeds that of the true distribution.

4.3 Examples 3-5

The next example we consider is illustrated in Fig. 9. Here we have an object with a piecewise constant profile in a background with linear variation. We invert using a model for a constant object and a quadratic background variation. The values for the object are intended to represent a dielectric scatterer with an air gap. It is important to note that this object can never be well represented using our low order polynomial model. The results of inverting with a model employing a constant object with a quadratic background are shown in Figs. 10(c)–(e). The strong localization performance demonstrated in these images in spite of this inherent model mismatch points to the

robustness of our approach to inversion ².

A similar experiment was repeated except that the values for the real and imaginary parts of the background were each corrupted by small amounts of appropriately scaled $[0, 1]$ additive uniform noise. Now neither the object nor the background can be exactly represented using the polynomial model. As shown in Fig. 10 we achieve highly accurate shape information along with useful information concerning the variations in the object as well as the background. Again, these results are indicative of the ability of a low order parameterization to withstand modeling inaccuracies. We note that for both of these examples, the results in Table 4 reflect the fact that we have sacrificed contrast accuracy for geometric fidelity. However, by modeling the contrasts as unknown constant, as expected we obtain estimated values that are close to the average values of the actual perturbations (which can be positive or negative) over the support of the anomaly. In Example 3 the computed real and imaginary perturbations are 8.9E-2 and -2.5E-2, respectively, compared to the means of the true perturbations to the real and imaginary parts, 8.3E-2 and -2.3E-3. Likewise, for Example 4 the calculated real and imaginary parts over the anomaly are 5.8E-3 and -7.01E-3 whereas the means of the true real and imaginary parts are 2E-2 and -2.4E-3.

Finally, in Fig. 11 we consider the problem of recovering a linearly varying object in a linearly varying background. Motivated by the CRB results, the object here is taken to be larger than those of the previous examples so that there will be sufficient signal to allow us to resolve the permittivity variations. As in the other cases, we again achieve strong localization. However there is some noticeable error in the estimates of the permittivity coefficients which is a reflection of the inherent difficulty in accurately obtaining this information. This example points to the need for further work in refining the permittivity estimates after having determined the boundary of the

²For this and the remaining experiments, we do not show the results of the BIM approach to inversion. Even after extensive fine tuning of the algorithm, it was impossible to obtain results comparable to those seen with the currently considered method.

object: model order determination and low order parameterizations should both play a role.

5 Conclusions and Future Work

We presented a new and potentially efficient technique for simultaneously solving the image formation and object characterization problems from scattered electric field data. The key idea was to formulate the perturbation in terms of a small number of parameters via a B-spline representation for the contour of the target. The examples illustrated that our technique can lead to good quality reconstructions: in particular, we found that it was possible to get good localization information even if the background is not homogeneous. A key issue associated with this strong performance is the ability to select good regularization parameters that balance the information content of the data with that of the constraints. In this work, we selected those parameters by hand. Clearly, an important area of future effort is the automation of this process.

Our experiments showed and the computed Cramer-Rao bounds confirmed that it is difficult, if not impossible, to get “linear” or even more complex information about the object unless it was sufficiently large, the noise sufficiently small, and the perturbation in the object was large relative to the perturbation in the background (i.e. the background needs to be nearly homogeneous).

One potential computational advantage to our technique is its inherent parallelism: cost evaluations can be done in parallel, making it computationally feasible to consider more complicated structures. For our reconstruction technique to capture more complex structures, however, we need to consider how to alter the complexity of the boundary representation by inserting and deleting basis elements in the B-spline representation. Solving this order determination problem in an efficient and close to optimal manner is far from trivial. In the future, we will also consider extensions of this work to the case of multiple objects. Finally, we hope to extend the work presented here to the 3D problem and to analyze its performance on real data.

K	total number of control points ($K - 2$ unique)
n_1	number of frequencies used to probe the earth
n_2	number of angles used to probe the earth
N	number of unknowns in subsurface discretization
M	number of data points for given θ, ω
NM	total number of data points
N_a	number columns in \mathbf{B}_1
N_b	number columns in \mathbf{B}_2

Table 1: Summary of index parameters. Note that the degrees of polynomials used to represent the object and the background are $N_a - 1$ and $N_b - 1$, respectively.

Example	SNR	True Obj.	True Back	Obj.	Back	λ_1	λ_2
1	20dB	0	0	0	0	3.28E-4	1.59E-4
2	20dB	0	0	0	0	6.0E-5	6.0E-5
3	30dB	PWC	1	0	2	1.55E-4	7.9E-5
4	20dB	PWC	1,rand	0	2	9.0E-5	6.0E-5
5	30dB	1	0	1	0	4.0762E-4	1.7015E-4

Table 2: Summary of experiments. Numbers in columns 3 to 6 indicate the degree of the polynomial used to generate the data (columns 3,4) or to reconstruct (columns 5,6). “PWC” indicates that the true object had piecewise constant perturbations in both the real and imaginary parts. “rand” indicates that random uniform perturbations were added to the real and imaginary parts of the background when generating data.

Abstract

Photothermal depth profilometry is formulated as a non-linear inverse scattering problem. Starting with the one dimensional heat diffusion equation, we derive a mathematical model relating arbitrary variation in the depth-dependent thermal conductivity to observed thermal wavefields at the surface of a material sample. The form of the model is particularly convenient for incorporation into a non-linear optimization framework for recovering the conductivity based on thermal wave data obtained at multiple frequencies. We develop an adaptive, multi-scale algorithm for solving this highly ill-posed inverse problem. The algorithm is designed to produce an accurate, low order representation of the thermal conductivity by automatically controlling the level of detail in the reconstruction. This control is designed to reflect both (1) the nature of the underlying physics which says scale should decrease with depth and (2) the particular structure of the conductivity profile which may require a sparse collection of fine scale components to adequately represent significant features such as a layering structure. The approach is demonstrated in a variety of synthetic examples representative of non-destructive evaluation problems seen in the steel industry.

Keywords: Adaptive signal representation, multiscale methods, B-splines, non-linear inverse scattering, photothermal depth profiling.

Running title: Multiscale adaptive inverse scattering

1 Introduction

One of the most promising applications of photothermal non-destructive evaluation (NDE) technology is in the area of *depth profilometry* (DP) [4, 8–13]. This technique uses a modulated laser beam to induce thermal waves in a material sample with the resulting wavefield amplitude and phase measured at the surface. The experiment is repeated for a number of modulation frequencies yielding a spectrum of observations. Assuming that the structure varies only with depth, the problem is to convert the measured spectrum into a depth-varying profile of a relevant physical property such as thermal conductivity [8], thermal effusivity [9], or thermal diffusivity [10, 12, 13].

Considerable work has been done in developing physical models and algorithms based on these models for reconstructing profiles. All models reported in the literature are based on the one dimensional, heat diffusion equation (HDE). In much of this work, the material is considered to be composed of layers where the physical properties assume simple functional forms. For piecewise constant layers, the HDE can be solved in terms of a recursively defined generalized reflection coefficient [4, 9]. In the limit of infinitesimally thin layers, the recursion converges to a non-linear Riccati equation. For finitely thick, piecewise linear layers the solution is given via a different recursively defined reflection coefficient [8].

An alternate approach based on the notion of a thermal harmonic oscillator (THO) has been pioneered by Mandelis and collaborators [11, 12]. Making a WKB approximation for variations of the thermal effusivity yields solutions to the HDE in terms of integrals of the thermal diffusivity. Using a particular functional form for this profile, analytic expressions have been reported for a semi-infinite medium and a finite depth inhomogeneity backed by a semi-infinite substrate [10].

Each of these physical models has been used as the basis for an inversion algorithm. Under suitable approximations (most notably, ignoring the non-linear term) the Riccati equation model reduces to a Laplace transform type relationship between the derivative of the log-effusivity and

the data [4, 9]. Tikhonov regularized, linear inversion methods are then used to determine the log effusivity [9]. While the details of the inversion methods for the piecewise constant and THO models are different, they both share a common structure in which the data are processed progressively from high to low modulation frequencies. The higher frequencies are used to estimate the profile structure in slices of the material closest to the surface while the lower frequency data provide information concerning the deeper variations. For the piecewise constant profile method, the width of these slices is determined *a priori* [8]. The THO method locally fits profiles of a predefined structure to slices whose widths are determined adaptively as the algorithm progresses [10, 13].

We pursue a different approach to the DP problem. Rather than considering solutions to the HDE for specific profiles or approximations to the physics, we employ a numerical implementation of the HDE which allows for exact solutions (up to discretization error) for arbitrary profiles. In particular, it is not necessary to assume that the thermal conductivity is slowly varying. The price for this flexibility is increased computational complexity. Thus, we also introduce a highly efficient, non-linear approximation to the exact solution. For the problem of interest in this paper, we show that this method, which is similar in nature to the Extended Born Approximation [5, 18], is about 20 times faster than the exact model with a loss in accuracy close to machine precision.

The use of this physical model allows us to formulate the profile reconstruction process as a non-linear inverse scattering problem in a highly lossy medium. Problems of this type are known to be ill-posed in that small perturbations in the data can lead to large amplitude, non-physical artifacts in a reconstruction. To stabilize the inversion process, one typically uses a *regularization* procedure. Our previous efforts in this field have included the use of wavelet-based regularization techniques for two dimensional, single frequency, non-linear inverse scattering problems [14, 15]. The use of wavelets was motivated by analysis which indicated that a given level of accuracy in a reconstruction required that the resolution in the estimated profile be space varying. The

data and the physics supported fine scale estimates in regions close to the detectors while coarser scale information could only be recovered further into the material sample. Representation of the unknown image using an orthonormal wavelet basis provided a convenient means of enforcing this variable resolution. Regularization was achieved in part by concentrating the information in the data on the recovery of a low order representation of the unknown comprised of relatively few fine scale wavelet coefficients supplemented by a small number of coarse scale coefficients

For the DP problem we build on this work using an alternate multiscale representation of the unknown profile. Rather than an orthonormal basis of wavelets, we use a collection of spline functions possessing a natural multiscale structure. Specifically, coarse scale elements can be expressed as linear combinations of finer scale splines [17]. By surrendering the orthonormality property of wavelets, we have a more flexible method for modeling the unknown profile.

As in [14] our inversion approach here is designed to produce a low order reconstruction in which the distribution of fine scale detail is determined in an automatic, controlled, and rational manner. The precise method for accomplishing this, however, is substantially different from our previous wavelet related efforts. Starting with a coarse scale set of functions, we iteratively refine the reconstruction to (a) add detail and then (b) prune away unnecessary degrees of freedom to obtain a more parsimonious description of the profile. The final estimate is comprised of functions at many scales whose spatial distribution is dictated adaptively by the data and the physical model. Like the results in e.g. [10] we tend to see fine scale detail close to the surface with coarser scale elements used deeper into the material. However, our approach involves no decomposition of the material into slices (predefined or virtual). Unlike the techniques in [8, 10] where low frequency data play no role in the structure of the reconstruction near the surface, here the data from all frequencies impact the entire structure of the estimated profile.

In §4 we show that limiting the number of degrees of freedom in the reconstruction is useful

for a number of reasons. First, the low dimensionality can lead to computational efficiencies. We demonstrate via numerical experiments that the adaptive algorithm can be substantially faster than a brute-force, fine scale reconstruction with little loss in accuracy. Additionally, our approach can lead to better reconstructions. As described in greater detail in §3.1, inversion requires the solution of a non-linear optimization problem and is thus prone to convergence to local minima of an associated cost function. By constraining the reconstruction using our adaptive approach, we show that it is also possible to converge to a lower cost point in solution space than is the case for a high dimensional, fine scale approach to inversion. Currently, we have observed these advantages only through simulation. An area of work is in the development of a more rigorous theory to understand the conditions where we might expect improved computational and/or reconstruction performance.

The remainder of this paper is organized as follows. In § 2, the physical model is developed. Our approach to inversion is provided in § 3. Here we formulate the basic problem in an inverse scattering context, define the spline functions, and describe the details of the adaptive algorithm. In § 4 we present examples of this method. Conclusions and future work are the subject of § 5.

2 Formulation of the Depth Profilometry Problem

2.1 Continuous Formulation

The DP problem of interest in this paper is the reconstruction of the thermal diffusivity profile based on observations of thermal waves obtained from illumination by a modulated laser source. The starting point is the one dimensional HDE with boundary conditions stated as follows:

$$\frac{d}{dz}\kappa(z)\frac{d}{dz}T(z) - i\omega\rho(z)c(z)T(z) = 0 \tag{1}$$

$$-\kappa(z)\frac{d}{dz}T(z) = \frac{1}{2}Q \quad z = 0 \tag{2}$$

$$T(z) = 0 \quad z \rightarrow \infty \tag{3}$$

where κ is the thermal conductivity, ρ the density and c the specific heat. $T(z)$ is the thermal wavefield, ω the angular modulation frequency, and Q the intensity of the laser light incident at the surface which is taken to be at $z = 0$. An $e^{i\omega t}$ time dependence for the source and T is assumed.

To produce a form of the model useful in an inverse scattering context we start by decomposing $\kappa(z)$ into the sum of a background component, $\kappa_b(z)$, and a perturbation of arbitrary magnitude, $\kappa_p(z)$. Generally the background is taken to be a nominal profile such as a halfspace as in [8, 12] or a well characterized material sample backed by air [10]. The goal of the inverse problem is the reconstruction of $\kappa_p(z)$ ¹. Inserting $\kappa = \kappa_b + \kappa_p$ into (1), we write the overall model as

$$(\mathcal{F}_b + \mathcal{F}_p)T = v \quad (4)$$

where we have defined the matrices of linear operators, \mathcal{F}_b and \mathcal{F}_p , and the source vector, v , as

$$\mathcal{F}_b = \begin{bmatrix} \frac{d}{dz}\kappa_b(z)\frac{d}{dz} - i\omega\rho(z)c(z) \\ b_0 \\ b_\infty \end{bmatrix} \quad \mathcal{F}_p = \begin{bmatrix} \frac{d}{dz}\kappa_p(z)\frac{d}{dz} \\ 0 \\ 0 \end{bmatrix} \quad v = \begin{bmatrix} 0 \\ \frac{1}{2}Q \\ 0 \end{bmatrix}. \quad (5)$$

The linear operator b_0 enforces the boundary condition, (2), and b_∞ implements (3).

We manipulate (4) to obtain a solution of the HDE in the form

$$T = (I + \mathcal{G}_b\mathcal{F}_p)^{-1}\mathcal{G}_bv \quad (6)$$

with $\mathcal{G}_b \equiv \mathcal{F}_b^{-1}$ the Green's operator for the boundary value problem (1)–(3) with $\kappa = \kappa_b$. Borrowing from the inverse scattering literature, the field computed with $\kappa_p = 0$ is termed the background field and is given as $T_b \equiv \mathcal{G}_bv$. The scattered field $T_s \equiv T - T_b$ is then

$$T_s = \mathcal{G}_b\mathcal{F}_pT = \mathcal{G}_b\frac{d}{dz}\kappa_p\frac{d}{dz}T \quad (7)$$

$$= \mathcal{G}_b\mathcal{F}_p(I + \mathcal{G}_b\mathcal{F}_p)^{-1}\mathcal{G}_bv. \quad (8)$$

where (7) follows from the definition of \mathcal{F}_p in (5) and (6) is used to obtain (8).

¹In theory, the specification of $\kappa_b(z)$ is somewhat arbitrary as the algorithm is designed to produce a κ_p such that $\kappa_b + \kappa_p$ is as accurate as possible. However, making κ_p “small” through as precise a description of κ_b as is possible does practically improve the convergence of the inversion.

The goal of the DP problem is to recover κ_p from observations of T_s taken at $z = 0$ for multiple modulation frequencies. In preparation for a description of the inversion algorithm in § 3, (7) indicates that $T_s(0)$ can be written as a linear functional of κ_p in which the functional explicitly depends on \mathcal{G}_b and dT/dz . Because $T(z)$ itself is dependent on κ_p , the functional also implicitly depends on the thermal conductivity. Thus letting y_k be the complex value datum taken at the k th frequency ω_k , we write

$$y_k = c_k(\kappa_p)\kappa_p \quad (9)$$

where c_k is the linear functional obtained from (7). In § 3.2 we provide an explicit formula for c_k in the context of a discretized model. The data vector comprised of y_k for $k = 1, 2, \dots, N_y$ is

$$y = \mathcal{C}(\kappa_p)\kappa_p \quad (10)$$

with \mathcal{C} being the column vector of c_k 's. The DP problem of interest in this work then is the recovery of κ_p from knowledge of y as well as the HDE model.

2.2 Discretization

To implement a solution to the DP problem requires a discretized form of the physical model. Here we use a standard first-order finite difference scheme for the HDE in (1)–(3). The field $T(z)$, and the physical properties $\kappa(z)$, $\rho(z)$ and $c(z)$ are sampled on a uniform grid of spacing h . First order differentiation w.r.t z then is represented using a bi-diagonal matrix, D_z , with $1/h$ on the main diagonal and $-1/h$ on the first super diagonal. For the homogeneous Neumann boundary condition, (3), we set to zero the last element in the vector of samples for the field T where we ensure that the boundary is taken far enough from the surface so that numerical artifacts are negligible.

To construct, the discrete form of the c_k in (9), consider the expression for T_s in (7). Under the discrete model we have

$$T_{s,k} = G_{b,k} D_z \mathcal{D}(\kappa_p) D_z T_k \quad (11)$$

with $G_{b,k}$ the matrix form of Green's operator for the k -th frequency, T_k the vector of samples of

the thermal field and similarly for κ_p and $T_{s,k}$. For a vector x , $\mathcal{D}(x)$ is the diagonal matrix whose (ii) th element is x_i . After some tedious but elementary algebra, it is not hard to show that from (11) we can write the surface value of the scattered wavefield under the discretized model as

$$T_s(z=0) = G_{b,k}(1, :)\mathcal{D}(T_k)D_z\mathcal{D}(D_zT_k)\kappa_p \equiv c_k(\kappa_p)\kappa_p \quad (12)$$

with $G_{b,k}(1, :)$ being the first row of the matrix G_b . From (12) we conclude that the discrete representation for the linear functional $c_k(\kappa_p)$ in (9) is the row vector $G_{b,k}(1, :)\mathcal{D}(T_k)D_z\mathcal{D}(D_zT_k)$.

The most computationally intensive part of this forward model is determination of the vector T_k . From (6), the discretized form of this calculation requires the solution of the linear system

$$(I + G_{b,k}F_p)T_k = G_{b,k}v. \quad (13)$$

Because the inversion algorithm requires systems of this form be solved hundreds if not thousands of times, there is significant motivation for seeking accurate approximations to the determination of T_k . The similarity of the DP problem to inverse electrical conductivity problems found in the geophysical community, lead us to consider a so-called Extended Born Approximation (EBA) to (13). A detailed theoretical treatment of this method may be found in [5, 18]. The practical implementation of the EBA for our problem amount to replacing the full matrix $I + G_{b,k}F_p$ by only its diagonal elements thereby greatly reducing the number of operations need to determine T_k . In § 4, we provide experimental verification of both the accuracy and efficiency of this method.

3 A Scale-Adaptive Algorithm for the DP Problem

We start by considering the fixed-scale solution to the DP problem in which we seek to recover κ_p directly from the data. The machinery developed here then forms the basis for the adaptive method developed later in this section.

3.1 The Fixed-Scale Solution

As is typically done for an inverse problem of the type considered here [15, 16, 18], we use our discretized model to define the estimate of κ_p as the solution to the following regularized least

squares cost function:

$$\hat{\kappa}_p = \arg \min_{\kappa_p} \|y - C(\kappa_p)\kappa_p\|_2^2 + \lambda^2 \|D_z \kappa_p\|_p^p. \quad (14)$$

The first term in (14) ensures that the estimate is consistent with the data. The second term plays the role of a regularizer and is used to help combat the ill-posedness. By varying p in the range 1 to 2 one can control the smoothness in the reconstruction. For $p = 2$, one obtains a traditional smoothness regularizer. As p approaches 1, the regularizer is more encouraging of forming profiles which have edges or other sharp discontinuities as might be found in certain NDE applications. With $p = 1$, one has a total variation (TV) regularization scheme [7, 19].

The regularization parameter, λ , in (14) determines the relative importance of the two terms on $\hat{\kappa}_p$. As $\lambda \rightarrow 0$, we demand that $\hat{\kappa}_p$ just fit the data. As mentioned in § 1, the resulting estimate tends to display high frequency, large amplitude artifacts. On the other hand, as $\lambda \rightarrow \infty$, the data play a limited role in influencing $\hat{\kappa}_p$ and we obtain overly smooth estimates. Proper selection of this parameter is a non-trivial problem [1, 6]. In this paper, we set λ by trial and error.

To solve (14) we start by writing $\|D_z \kappa_p\|_p^p = g(\kappa_p)^T g(\kappa_p)$ with g the vector whose i th element is $[D_z \kappa_p]_i^{p/2}$. Thus (14) is formulated as a non-linear least squares optimization problem:

$$\hat{\kappa}_p = \arg \min_{\kappa_p} e^T(\kappa_p) e(\kappa_p) \quad (15)$$

$$e(\kappa_p) = \begin{bmatrix} y - C(\kappa_p)\kappa_p \\ \lambda g(\kappa_p) \end{bmatrix} \quad (16)$$

Eq. (15) is solved using the `leastsq` routine provided in Matlab's Optimization Toolbox. For a given κ_p this program requires the ability to evaluate the RHS in (15) and a method for computing the Jacobian of the vector e in (16) with respect to each element of κ_p . The cost evaluation is done using the equations developed in the previous section. We approximate the Jacobian, J , as

$$J = \begin{bmatrix} -C(\kappa_p) \\ \frac{\partial g}{\partial \kappa_p} \end{bmatrix}. \quad (17)$$

After some straightforward calculus, it is not hard to show that

$$\frac{\partial g}{\partial \kappa_p} = \frac{p}{2} \mathcal{D}(g)^{-p/2} \mathcal{D}(\text{sign}(g)) D_z$$

with $\text{sign}(g)$ the vector whose i th element is the signum of g_i . Note that in (17) we ignore the dependence of C on κ_p . This is the primary motivation for formulating the physical problem in the manner of §2. This approximation is closely related to the Born Iterative Method [2] for problems in which the ρc product in (1) is to be recovered rather than κ .

3.2 Adaptive Multiscale Inversion

As discussed in §1, a key issue of interest in this paper is the determination of a low order, multiscale representation for the vector κ_p as a means of reducing the complexity of the inversion process and improving the quality of the ultimate reconstruction by “appropriately” distributing fine scale information. To achieve this, we constrain κ_p to live in the linear span of a set of vectors where we adaptively determine both the vectors and the required expansion coefficients. Formally, we consider representation of κ_p of the form

$$\kappa_p = \sum_{i=1}^{N_b} b_i a_i = B a \quad (18)$$

where b_i is the i th vector, a_i the expansion coefficient, B the matrix whose i th column is b_i , and a the vector of a_i . Note that a is of length N_b .

Using (18) and (15), the determination of $\hat{\kappa}_p$ now reduces to the estimation of the a_i via

$$\hat{a} = \arg \min_a e^T(Ba) e(Ba) = \arg \min_a \|e(Ba)\|_2^2 \quad (19)$$

where $e(Ba)$ is (16) evaluated at the vector $\kappa_p = Ba$. Letting N be the length of κ_p , then typically we have $N_b \ll N$ so that (19) is a far smaller optimization problem than (15). In the remainder of this section, we describe the family of vectors used in our approach as well as the methods we have developed to adaptively determine those b_i to include in $\hat{\kappa}_p$.

The b_i vectors are sampled versions of a family of continuous functions which satisfy the following

two scale dilation equation [17]

$$b(z) = \sum_{k=0}^{N_k-1} \alpha_k b(2z - k). \quad (20)$$

In words, (20) says that the function b can be expressed as a linear combination of dilated and translated versions, $b(2z-k)$, of itself. While specification of the coefficients α_i can lead to many functions which satisfy (20), including wavelets, here we are concerned with B-splines [17, Chap. 7.4]. For example, with $\alpha_0 = \alpha_1 = 1$, the $b(z)$ satisfying (20) is nothing more than the box function from $z = 0$ to $z = 1$. Such zeroth order splines form a basis for piecewise constant functions. With $\alpha_0 = \alpha_2 = 1$ and $\alpha_1 = 2$, we obtain a hat function, or first order B-spline, which is piecewise linear.

Here we employ piecewise quadratic B-splines generated using $\alpha_0 = \alpha_3 = 1$ and $\alpha_1 = \alpha_2 = 3$. In Figure 1, we illustrate these functions on two spatial scales: a coarse scale at the top and a finer scale at the bottom. Note that the relative spacing of the spline functions is proportional to their width. Additionally, because these functions satisfy (20), wide functions on one scale can be expressed as linear combinations of narrow functions on the next scale. For example, the highlighted element shown at the top of Figure 1 can be decomposed via (20) in terms of the fine scale functions in the bottom panel. We represent the relationship among these functions using a graph as shown in Figure 2. The nodes in the graph represent the functions (or associated expansion coefficients) and the edges indicate the links from one scale to the next.

We make use of the non-linear least squares formulation of § 3.1 and the functions defined above to obtain a reconstruction of κ_p using the algorithm outlined in Fig. 3. We start with a low order, coarse scale collection of quadratic B-splines. With these b_i , we estimate a set of expansion coefficients to get a rough $\hat{\kappa}_p$. The remainder of the algorithm is a loop where the current collection of vectors is alternately refined and then unneeded detail is pruned away. The goal is to provide sufficient flexibility to add arbitrary detail to $\hat{\kappa}_p$ followed by a stage in which we determine which, if any, degrees of freedom associated with this detail were warranted. Those not needed are removed.

While one might consider many methods to accomplish this objective, in the following paragraphs, we detail an approach which we have found to work well at least for the DP problem.

In the refinement stage, we replace all b_i in our representation of $\hat{\kappa}_p$ by their finer scale children². This allows for the recovery of finer scale information at the expense of a higher order representation. Once the new collection of vectors is constructed, we solve for a new vector of expansion coefficients to produce a finer scale estimate of κ_p . While this requires the solution of a new non-linear least squares problem, the coarse scale estimate is used to initialize the finer scale reconstruction procedure to speed convergence. Specifically, the a_i for each child is initialized using the average of the previously generated parent estimates. From Figure 2, assume that vectors 3-8 had just been replaced by 9-22. Then, e.g., the initial values for a_{13} and a_{14} would both be $\frac{a_4+a_5}{2}$.

After refining the estimate, we next remove unnecessary detail. The goal here is to reduce the complexity of the model by

- **Coarsening** Replacing fine scale children with their parents in regions where such detail is not warranted
- **Pruning** Removing from the representation vectors which contribute little to $\hat{\kappa}_p$

Coarsening is done in a sequence of steps in which limited detail is removed at each stage until we can no longer represent the current estimate of κ_p to within some predetermined tolerance. A similar procedure is carried out for pruning except that we remove from the estimate in a one-by-one manner vectors whose $|a_i|$ are small. The result is a lower order model which is a “small” perturbation of the optimal estimate computed from the previous optimization step.

As illustrated in Fig. 4, we begin coarsening by looking for all collections vectors in our current B matrix which represent a complete set of children for a given parent. For example, in Figure 2, vectors 13-16 are a complete set of children for 5. For each such children-parent set, we consider

²Obviously, those b_i already at the finest scale are not refined.

a new collection of vectors obtained by replacing those fine scale children with *all* of their coarse scale parents keeping the remaining members of the current collection the same. Again, referring to Figure 2 suppose that the current B matrix was comprised of vectors 9-22. One set of vectors considered by the pruning process would be 9-12, 4-6, and 17-22. Here 13-16 are removed and replaced by all relevant parents, in this case 4, 5, and 6. Another possible configuration is 9, 10, 3-5, and 15-22 where 11-14 are replaced by 3-5.

This replacement strategy yields some finite number of possible sets of vectors for representing κ_p with each set having fewer members than the current one. To determine which, if any collection is selected, we project $\hat{\kappa}_p$ onto the linear span of the vectors in each set. Let B_i be the matrix constructed from one such coarse set of vectors. The projection, $\hat{\kappa}_{p,i}$, is computed as $\hat{\kappa}_{p,i} = B_i B_i^\dagger \hat{\kappa}_p$ where B_i^\dagger is the pseudo-inverse of B_i [3, p. 243]³. As explained in Appendix 6, to evaluate the utility of $\hat{\kappa}_{p,i}$ it is useful to compute a weighted error, $\|J(\hat{\kappa}_p - \hat{\kappa}_{p,i})\|$ where J is given in (17) and is evaluated at $\hat{\kappa}_p$. If the minimum weighted error over all i is less than some threshold, we replace the fine scale collection with the elements from the new, coarsened set, otherwise we stop. If we do not stop, then the pruning process is repeated. Specifically, if B_j^* denotes the selected set, we replace children in B_j^* by parents again using the relative norm criteria just described. If the minimum error still is not too small, B_j^* is replaced by a new, smaller set and the process continues.

To do pruning, we start by removing from the final set of vectors produced by coarsening that vector whose $|a_i|$ is smallest. As is done in pruning, we look at the weighted error between $\hat{\kappa}_p$ and its projection onto the remaining vectors. If this error exceeds a threshold, then we stop, otherwise, the procedure continues using the expansion coefficients associated with this projection.

After pruning is finished, we pass the new collection of expansion vectors into the non-linear

³Because we allow B_i to contain B-spline vectors at multiple scales and arbitrary dyadic shifts, it is possible that elements of B_j will be linearly dependent hence the need to use a pseudo-inverse. Both theoretically and practically this linear dependence causes no difficulty for the algorithm in this paper.

least squares solver to obtain the best estimate of the conductivity using this coarsened set. Again, another optimization is performed. As described in the previous paragraphs however, the pruning process yields a low order collection of vector which still supports an accurate approximation of $\hat{\kappa}_p$. Thus, it is reasonable to assume that the set of optimal expansion coefficients should be close to the coefficients obtained by projecting $\hat{\kappa}_p$ onto the coarse set. Throughout our numerical experiments, we have found that initializing in this way does in fact lead to rapid convergence of the non-linear least squares routine for this stage of the algorithm.

This refinement-pruning loop is continued until the relative difference of the two-norm between estimates produced at the end of two successive pruning stages is below some threshold. We note that this approach does not guarantee a monotonic decrease in the cost function as we change the vectors in B . Indeed, we have seen in our experiments that the optimal κ_p obtained after a coarsening/pruning step can have a higher cost than the previous $\hat{\kappa}_p$ comprised of a larger number of expansion vectors. As examined in Appendix 6 however, the choice of weighted error criteria for accepting a coarsened or pruned collection of vectors is constructed in a way to limit the resulting rise in cost. Thus, while the cost may increase, we guarantee that this increase is bounded.

4 Examples

Here we consider the performance of our inversion approach on a variety of profiles. The background is meant to model case hardened steel as in [8] so $\kappa_b = 0.45 \text{ W cm}^{-1} \text{ K}^{-1}$, $\rho = 7.7 \text{ g cm}^{-3}$, and $c = 0.48 \text{ J g}^{-1} \text{ K}^{-1}$. In all cases depth profiles are constructed for z between 0 and 400 μm from the surface based on thermal wave data from 16 logarithmically spaced frequencies in the range 10 to 10000 s^{-1} . The signal to noise ratio on T_s is taken to be 30 dB.

Over the 400 μm range of interest, we discretize the forward model on a grid of 256 equally spaced points corresponding to an interpoint spacing of about 1.57 μm . All data vectors are

generated using the exact, discretized forward model while the inversion algorithm makes use of the EBA-type model described at the end of §2.2. For all examples, ϵ , the tolerance parameters used in the coarsening and pruning stages was $1e - 4$. The threshold used to terminate the refinement-pruning loop was 5%. In all cases, $\lambda = 1$ (this value was determined by trial and error) and the reconstruction algorithms were initialized with zero for the perturbation. Finally, there were a total of five scales worth of B-spline functions that could be used in the construction of $\hat{\kappa}_p$.

A Monte-Carlo analysis was used to evaluate the Extended Born Approximation to the true scattering model. We started by generating 100 random κ_p profiles via

$$\kappa_p = \sum_{i=1}^{17} a_i b_i$$

where the b_i are a collection “mid-scale” B-splines shown in Figure 5(a) and the a_i were taken to be zero mean, independent Gaussian random variables with standard deviation 20^4 . The goal here was to produce profiles which were not merely small perturbations on the background. Some samples are shown in Figure 5(b). For each profile, we solved the forward problem using the exact method and the EBA. Over the 100 trials, the average relative error between the exact and approximate data vectors was about 10^{-13} while the EBA required about 18 times fewer floating point operations than the exact model. Thus, for the problems of interest here, the EBA represents a highly efficient, essentially exact solver for the HDE.

We start by examining the performance of our approach for a profile with a layer-like inclusion shown as the solid line in Figure 6(a). To gauge the average performance in the presence of noise, in this and the next example, we performed the inversion ten times for ten difference realizations of the additive disturbance. In Figure 6(a) the dashed line is a plot of the average reconstruction for the adaptive method while the results of inverting using the finest scale grid of 256 points are given by the dashed-dot line. Here we set $p = 1.1$ in (14) to obtain an edge-preserving type of regularization.

⁴Too keep κ positive, we set to zero any values of $\kappa_p < 45$, where 45 is the background thermal conductivity.

In practice it would be necessary to also develop a method for choosing this quantity; however for the sake of simplicity, as with λ , we assume that p is known *a priori*.

Figure 6(a) shows that, on average, the results of using the adaptive approach are comparable to those of a fixed, fine scale inversion. For the adaptive method, the peak value of the reconstruction is slightly closer to that of the true profile. However, for the fixed scale method, the average reconstruction is slightly flatter over the region of the layer. The average mean square error between the two methods differed by about 1% with the fine scale case having smaller average error.

As stated in the Introduction, one of the potential advantages of the adaptive method over a fixed scale inversion is computational. To explore this issue, we “instrumented” the `leastsq` procedure to collect statistics of the inversion process. For one of the ten runs in Figure 6(b) and (c), we plot the value of the cost function and the value of the error against the number of times the inversion routine made a call to evaluate the cost. Since cost evaluation requires the evaluation of the HDE model which is the most computationally intensive step in the process, the number of times the cost function is called is a valid measure of the complexity of the inversion procedure. Also, for the adaptive approach, the plot displays the cost and error for *all* refinement-pruning stages of the algorithm and thus is an accurate portrayal of the complexity of the entire routine.

We observe from Figure 6(b) and (c) that the adaptive method converges at a faster rate than the fine scale method. Thus, while the two methods converge essentially to the same profile, by constraining the inversion, we get closer to the final result faster. We note that this behavior was true in general for all ten runs. Moreover, because the adaptive approach required fewer unknowns, for this problem, significantly fewer floating point operations were needed. The average number of unknowns in the final reconstruction over the ten runs was about 19 for the adaptive approach versus 256 for the fine scale method. Reduction in the size of the inverse problem translated into a floating point count that was about 2.86 times smaller for the adaptive method than the fixed scale

inversion. Thus, for this problem, the adaptive method produces essentially the same reconstruction as a fixed scale technique at a significantly reduced level of complexity.

In addition to this quantitative advantage, the adaptive inversion also yields interesting qualitative results. By examining *which* vectors are used in the reconstruction, we see that the adaptive approach placed limited detail precisely where it belongs in a reconstruction using fewer, coarser scale vectors where κ_p varies more slowly. Indeed, Figure 6(a) indicates that for both fixed and adaptive inversions, the edge closer to the surface is recovered more accurately than the edge deeper into the medium. For the same run used to produce the graphs in Figure 6, we show in Figure 7(a) the individual vectors which contribute to the final adaptive reconstruction. We see in particular that most of the fine scale detail is distributed near the leading edge with wider, coarser scale vectors used for much of the remainder of the reconstruction. This point is further highlighted in Figure 7(b) where we plot as a function of depth, the finest scale in the reconstruction. Specifically, at each point, z , there may be a number of vectors whose support includes this point. Figure 7(b) then shows the scale of the finest vector having support at each position. Larger numbers imply finer scale and for these examples, there are 5 scales of B-splines which may be used.

Typically, for a diffusive inverse problem of the type considered here, physical intuition dictates that the level of detail decreases as a function of increasing depth due to the heavy damping of the thermal waves. While this may be true in general, it also ignores the fact that one may want limited fine scale detail to support the reconstruction of important sharp features (e.g. edges) which may be present in the profile. The results in Figure 7 demonstrate that the algorithm described in this paper is capable of adapting the detail in the reconstruction in a way which reflects both the underlying physics as well as the structure of the particular profile. The general trend is a decrease in resolution as a function of depth; however, we see an increase in the level of detail specifically in the neighborhood of the edge. Thus, to obtain the shaper profile, the algorithm automatically

chooses to distribute some fine scale degrees of freedom near the feature of interest.

In Figs. 8 and 9, we examine the results of the method represented in this paper for a smoother profile. For this analysis, we set $p = 2$ in (14) to obtain a more standard smoothness type of regularizer. The results here indicate a different advantage the adaptive method may have with respect to a fixed, fine scale inversion. Figure 8 shows that over the ten runs used to evaluate the performance of the algorithm, on average the fixed scale approach converges to a far from global minimum of the cost function. Alternatively, by constraining the search space, the adaptive inversion routine essentially settles into a lower cost local minimum which is also of much lower error. The convergence curves for one of the runs shown in Figure 8(b) and (c) provide further evidence of this behavior. For this problem, despite the fact that the adaptive approach uses on average about 11 vectors, approximately 16% more floating point operations are required versus the finest scale inversion. Thus, in contrast to the first example, here we see a slightly higher computational cost producing a significantly improved reconstruction.

Finally, in Figure 9, the constituent components of the one of the ten final reconstructions are displayed. We see here that the absence of an edge or other sharp feature in κ_p has resulted in coarser scale vector being used here relative to those in Figure 7. Generally, the trend is one of decreasing resolution as a function of depth.

5 Conclusions and Future Work

We have described an inverse scattering type of approach to the photothermal depth profilometry problem. Using the heat diffusion equation as the basic physical model, a measurement model is derived based on a decomposition of the thermal conductivity into the sum of a background component and an arbitrary sized perturbation. The physical model is cast in a form appropriate for use in a regularized, iterative inversion scheme. We have presented an accurate, low complexity

approximation to the exact HDE model having the form of an Extended Born Approximation.

We have introduced and explored the performance of an inversion technique designed to focus the information in the data on a small number of carefully selected degrees of freedom. Specifically, we have made use of multiscale, B-spline functions to construct an adaptive algorithm in which the presence of fine scale detail in the reconstruction is carefully controlled. The algorithm is based on an iterative loop in which the current set of vectors is first refined, to allow more detail, and subsequently pruned, to remove unwarranted degrees of freedom. The utility of this approach has been demonstrated on a number of simulated examples representative of applications of this technology to the non-destructive evaluation of case hardened steel. We plan on testing this method on experimental data in the near future.

In comparing the adaptive method to a fixed, fine scale inversion we have seen two types of behavior. For one problem the two approaches produce essentially the same reconstruction but the computational cost of the adaptive method is far smaller than that of the fixed scale technique. Alternatively, for a second problem, the adaptive method was shown to converge to a far lower cost of the optimization function; however the price paid for this improved performance was about a 20% increase in complexity. One important objective in the future is to develop a theoretical understanding of the circumstances (classes of profiles, noise conditions, sensing system parameters, etc.) under which one might expect one of these two types of performance.

6 Appendix 1

Because the basis coarsening and pruning steps remove degrees of freedom from the representation of $\hat{\kappa}_p$, it is possible value of the cost function will rise after these procedures. The objective of this appendix is to derive a method for accepting a coarsened set of vectors which guarantees that the relative rise in cost is no larger than some predefined threshold.

Referring to (15) we define $F(\kappa_p)$ as $e^T(\kappa_p)e(\kappa_p)$. Let us assume that we have a fine scale estimate, $\hat{\kappa}_p$ which we wish to coarsen. Because $\hat{\kappa}_p$ is by definition a solution to the non-linear least squares optimization problem for some B , a second order Taylor expansion of F about $\hat{\kappa}_p$ yields []

$$F(\hat{\kappa}_p + \delta) \approx F(\hat{\kappa}_p) + 1/2\delta^T H \delta \quad (21)$$

where H is the Hessian of the cost function. Since δ is small, the Hessian is well approximated by $J^T J$ [] with J the Jacobian of e evaluated at $\hat{\kappa}_p$. Thus, after some algebra we write the relative change in cost due to a perturbation δ from $\hat{\kappa}_p$ as

$$\frac{F(\hat{\kappa}_p + \delta) - F(\hat{\kappa}_p)}{F(\hat{\kappa}_p)} \approx \frac{\|J\delta\|_2^2}{2F(\hat{\kappa}_p)}. \quad (22)$$

From § 3.2, for the coarsening problem, $\delta = \hat{\kappa}_p - \hat{\kappa}_{p,i}$. Thus, to ensure that the relative change in the cost rises by at most ϵ , we require that $\|J(\hat{\kappa}_p - \hat{\kappa}_{p,i})\|_2^2 < 2\epsilon F(\hat{\kappa}_p)$.

A shape reconstruction method for electromagnetic tomography using adjoint fields and level sets

Oliver Dorn* Eric L. Miller* Carey M. Rappaport *

March 20, 2000

Abstract

A two-step shape reconstruction method for electromagnetic (EM) tomography is presented which uses adjoint fields and level sets. The inhomogeneous background permittivity distribution and the values of the permittivities in some penetrable obstacles are assumed to be known, and the number, sizes, shapes, and locations of these obstacles have to be reconstructed given noisy limited-view EM data. The main application we address in the paper is the imaging and monitoring of pollutant plumes in environmental cleanup sites based on cross-borehole EM data. The first step of the reconstruction scheme makes use of an inverse scattering solver which first recovers equivalent scattering sources for a number of experiments, and then calculates from these an approximation for the permittivity distribution in the medium. The second step uses this result as an initial guess for solving the shape reconstruction problem. A key point in this second step is the fusion of the 'level set technique' for representing the shapes of the reconstructed obstacles, and an 'adjoint field technique' for solving the nonlinear inverse problem. In each step, a forward and an adjoint Helmholtz problem are solved based on the permittivity distribution which corresponds to the latest best guess for the representing level set function. A correction for this level set function is then calculated *directly* by combining the results of these two runs. Numerical experiments are presented which show that the derived method is able to recover one or more objects with nontrivial shapes given noisy cross-borehole EM data.

1 Introduction

In this paper, we investigate the retrieval of an unknown number of penetrable objects (inclusions) imbedded in an inhomogeneous background medium based on observations of electromagnetic (EM) fields. The electromagnetic characteristics (permittivity and conductivity) of the background medium as well as of the material forming the inclusions are assumed to be known, but the main topological information concerning the number, sizes, shapes, and locations of the inclusions is missing and has to be reconstructed from the EM data.

One possible technique for using EM fields in cross-borehole tomography is ElectroMagnetic Induction Tomography (EMIT) [3, 18, 44, 49, 50, 51] which typically operates at frequencies between 1 to 20 kHz. In this frequency band, electromagnetic fields tend to diffuse rather than propagate as waves through the Earth. Penetration depths of 100 m or more are possible at these low frequencies, but the diffusional behavior of the fields makes the inverse problem severely ill-posed.

However, if the typical distances in the area of interest are not much larger than 10-20 m, we can use EM fields in the higher frequency band of 5 to 30 MHz instead. The wavelengths of these fields are typically between 2-15 m in moist soil, where the relative dielectric constant is typically around 20 [48]. Therefore, we can make use of wave propagation phenomena in the inversion process. In the present paper, we address this situation. The main application we have in mind is the imaging and monitoring of pollutant plumes at environmental cleanup sites given cross-borehole EM data, where the distances of the boreholes are not much larger than 10-20 m.

We assume that the known conductivity distribution is positive but small everywhere, and that the permittivity distribution in the medium has to be recovered. Inside the pollutant plumes, the permittivity is assumed to be constant with a known value, and the background permittivity is arbitrary but also known. Therefore, the task is to find the *number, shapes, sizes and locations of the pollutant plumes* from cross-borehole data gathered for a small number (less than 10) of frequencies. No

topological constraints are made on the shapes of these plumes. For example, they are allowed to be multiply connected, and to enclose 'cavities' or 'holes' filled with background material.

The main difficulties which arise in this situation are 1.) We want to allow for an (arbitrary) inhomogeneous background permittivity distribution in the inversion; 2.) The inverse problem is usually strongly nonlinear because of the high contrast of the permittivity values inside the plumes to the background medium; 3.) The data in our application are typically noisy and have only limited view; and 4.) The number of the plumes is typically unknown, and their shapes can have a complicated geometry.

In this paper, we propose a new shape reconstruction method which works in a two-step fashion in order to overcome these difficulties.

The first step of this combined inversion scheme plays the role of an initializing procedure for the second step, and employs a 'source-type' inversion method (which is described in more details in section 5) to deal with the high nonlinearity in the problem due to the presence of strong scatterers.

Then, the second step directly starts with the outcome of this initializing procedure, and continues by using a combination of the 'adjoint field technique' and a level set representation of the shapes until the inversion task is completed. Using a level set representation in this second step enables us to easily describe and keep track of complicated geometries which arise during the inversion process.

Both steps use an 'adjoint field technique' for the inversion which has the very useful property that the inverse problem can be solved approximately by making two uses of the same forward modelling code. Using a somewhat oversimplified description of our technique, the updates to the level set function are obtained by first making one pass through the code using the permittivity distribution corresponding to the latest best guess of the level set function, and then another pass with the adjoint operator applied to the differences in computed and measured data. Then the results of these two calculations are combined to determine updates to the level set function. The resulting procedure is iterative, and can be applied successively to parts of the data, e.g., data associated with one transmitter location and one frequency can be used to update the model before other transmitter locations and other frequencies are considered. This general procedure has several of the same advantages as wave equation migration in reflection seismology [10] and is also related to recent methods in EM migration introduced in Zhdanov *et al.* [51]. A similar technique has been successfully applied recently as part of an iterative nonlinear inversion scheme in [17, 18, 33].

The *level set method* was originally developed by Osher and Sethian for describ-

ing the motion of curves and surfaces [35, 41]. Since then, it has found applications in a variety of quite different situations. Examples are image enhancement, computer vision, interface problems, crystal growth, or etching and deposition in the microchip fabrication. For an overview we refer to [42].

The idea of using a level set representation as part of a solution scheme for inverse problems involving obstacles was first suggested by Santosa in [40]. More recently, a similar method was applied to a nonlinear inverse scattering problem by Litman *et al.* in [28]. In that work, an inverse transmission problem in free space is solved by a controlled evolution of a level set function. This evolution is governed by a Hamilton-Jacobi type equation, whose velocity function has to be determined properly in order to minimize a given cost functional.

The approach developed here does not lead to a Hamilton-Jacobi type equation. We follow an optimization approach, and employ a very specific inversion routine (an adjoint field technique) for solving it. This has the advantage that we do not have to propagate the level set function explicitly by computing a numerical Hamiltonian. Instead, our inversion routine provides us in each step with an update that has to be applied *directly* to the most recent level set function. Doing so, we automatically 'propagate' the level set function until the method converges.

This gain in simplicity, however, has its price. In order to arrive at an efficient scheme which is practically useful as well as easy to implement, we will apply some suitable approximations when deriving the algorithm. We will point out and discuss these approximations in those sections of the paper where they are applied.

For interesting approaches to solving shape recovery problems in various applications we refer to [23, 24, 26] and to the references therein. For alternative approaches to the shape reconstruction method in geophysical applications see [30, 39, 43] and the references therein. The treatment of more general inverse scattering problems is for example addressed in [4, 8, 11, 12, 15, 22, 31, 33, 38].

The paper is organized as follows. In section 2 we will present the basic equations of 2D EMs in a form convenient for development of the shape reconstruction technique. In section 3 we formulate the shape reconstruction problem and introduce the level set formulation of this problem. In section 4, we derive the basic shape reconstruction algorithm using level sets and adjoint fields. Section 5 describes how to calculate a suitable initialization for the shape reconstruction algorithm. In Section 6 numerical experiments are presented which demonstrate the performance of the algorithm in different situations. The final section summarizes the results of this paper and indicates some directions for future research.

2 The physical experiment

2.1 The Helmholtz Equation

We consider the 2D Helmholtz Equation

$$\Delta u + k^2(x)u = q(x) \quad \text{in } \mathbf{R}^2, \quad (1)$$

with complex wavenumber

$$k^2(x) = \omega^2 \mu_0 \epsilon_0 \left[\epsilon(x) + i \frac{\sigma(x)}{\omega \epsilon_0} \right]. \quad (2)$$

Here, $i^2 = -1$, ω denotes the angular frequency $\omega = 2\pi f$, μ_0 is the magnetic permeability in free space $\mu_0 = 4\pi \times 10^{-7}$ Henrys per meter, ϵ_0 is the dielectric permittivity in free space $\epsilon_0 = 8.854 \times 10^{-12}$ Farads per meter, ϵ is the relative dielectric permittivity (dimensionless), and σ is the electric conductivity in Siemens per meter. The form of (2) corresponds to time-harmonic line sources $\tilde{q}(x, t)$ which have a time-dependence $\tilde{q}(x, t) = q(x)e^{-i\omega t}$. For these sources we require that there exists a radius $r_0 > 0$ such that $\text{supp}(q) \subset\subset B_{r_0}(0)$, where $B_r(x) = \{y \in \mathbf{R}^2, |x - y| < r\}$ denotes the open ball centered in x with radius $r > 0$. For simplicity we assume throughout the paper that we can find a ball $B_R(0)$ with $R > r$ such that the complex wavenumber $k^2(x)$ is constant with value k_0^2 in $\mathbf{R}^2 \setminus B_R(0)$, and that for this k_0 the field u generated by (1) satisfies the Sommerfeld radiation condition

$$\lim_{r \rightarrow \infty} \sqrt{r} \left(\frac{\partial u}{\partial r} - ik_0 u \right) = 0 \quad (3)$$

with $r = |x|$ where the limit is assumed to hold uniformly in all directions $x/|x|$. With this assumption, the problem (1)-(3) possesses a uniquely determined solution u in \mathbf{R}^2 [12].

Furthermore we will consider in this paper only the case that the conductivity is positive everywhere, $\sigma > 0$ in \mathbf{R}^2 , and that it is small in some sense which will be specified later. Typical values in our geophysical examples will be $\sigma \approx 10^{-3} - 10^{-4}$ Siemens per meter or less [48].

We want to introduce some notation here which will be useful in the following. We denote the wavenumber $k^2(x)$ in short form by

$$k^2(x) = \kappa(x) = a\epsilon(x) + ib\sigma(x), \quad a = \omega^2 \mu_0 \epsilon_0, \quad b = \omega \mu_0. \quad (4)$$

We only consider positive frequencies $\omega > 0$ such that $a, b > 0$.

2.2 Formulation of the inverse problem

We assume that we are given p different source distributions q_j , $j = 1, \dots, p$. For each of these sources, data are gathered at the detector positions x_d , $d = 1, \dots, D_j$, for various frequencies f_k , $k = 1, \dots, K$. The total number of receivers D_j , as well as their positions x_d , might vary with the source q_j . We assume, for simplicity in the notation, that these positions do not depend on the frequency f_k . This restriction is, however, not necessary for the derivation of the inversion method. We require that there exists a radius $r_1 > 0$ such that all receiver positions are inside the ball of radius r_1 , i.e. $x_{jd} \in B_{r_1}(0)$ for all $d = 1, \dots, D_j$, $j = 1, \dots, p$.

For a given source q_j and a given frequency f_k we collect a set of data \tilde{G}_{jk} which is described by

$$\tilde{G}_{jk} = \left(\tilde{u}_{jk}(x_{j1}), \dots, \tilde{u}_{jk}(x_{jd}), \dots, \tilde{u}_{jk}(x_{jD_j}) \right)^T \in Z_j \quad (5)$$

with $Z_j = \mathbb{C}^{D_j}$ being the data space corresponding to a single experiment using one source and one frequency only. In (5), the fields \tilde{u}_{jk} solve (1)-(3) with the correct permittivity distribution $\tilde{\epsilon}(x)$, i.e.

$$\Delta \tilde{u}_{jk} + [a_k \tilde{\epsilon}(x) + ib_k \sigma(x)] \tilde{u}_{jk} = q_j(x) \quad \text{in } \mathbb{R}^2 \quad (6)$$

with

$$a_k = \omega_k^2 \mu_0 \epsilon_0, \quad b_k = \omega_k \mu_0, \quad \omega_k = 2\pi f_k. \quad (7)$$

In a slightly more formal way, we define for a given source q_j the measurement operator M_j acting on solutions u of (1) by

$$M_j u = \left(\int_{\mathbb{R}^2} u(x) \delta(x - x_{jd}) dx \right)_{d=1, \dots, D_j}^T. \quad (8)$$

With this notation, (5) is written as

$$\tilde{G}_{jk} = M_j \tilde{u}_{jk}, \quad j = 1, \dots, p, \quad k = 1, \dots, K. \quad (9)$$

We gather these data sets $\tilde{G}_{j,k}$ for all sources q_j , $j = 1, \dots, p$, and all frequencies f_k , $k = 1, \dots, K$, and the aim is to recover from this collection of data sets

$$\tilde{G} = (\tilde{G}_{1,1}, \dots, \tilde{G}_{p,K})^T \quad (10)$$

the unknown parameter distribution $\tilde{\epsilon}(x)$ in the domain of interest.

In the application of *EM cross-borehole tomography*, the sources and receivers are typically situated in some boreholes, and the permittivity distribution ϵ (and/or the conductivity distribution σ) between these boreholes has to be recovered from

the gathered data. In the 2D geometry considered here, typical sources are time-harmonic line sources which can be modelled in (1) by

$$q_j(x) = J_j \delta(x - x_j), \quad j = 1, \dots, p, \quad (11)$$

where x_j denotes the 2D coordinates of the j -th line source, $j = 1, \dots, p$, and the complex number J_j is the strength of the source. We will use these sources in our numerical experiments in section 6.

3 The shape reconstruction problem

In this section we formulate the shape reconstruction problem which we want to solve, and cast it in a form which makes use of the level set representation of the domains.

3.1 Shape reconstruction and inverse scattering

To start with we introduce some terminology which we will use throughout the paper.

Definition 3.1 *Let us assume that we are given a constant $\hat{\epsilon} > 0$, an open ball $B_r(0) \subset \mathbb{R}^2$ with $r > \max(r_0, r_1) > 0$, and a bounded function $\epsilon_b : \mathbb{R}^2 \rightarrow \mathbb{R}$. We call a pair (Ω, ϵ) , which consists of a compact domain $\Omega \subset\subset B_r(0)$ and a bounded function $\epsilon : \mathbb{R}^2 \rightarrow \mathbb{R}$, admissible if we have*

$$\epsilon|_{\Omega} = \hat{\epsilon}, \quad \epsilon|_{\mathbb{R}^2 \setminus \Omega} = \epsilon_b|_{\mathbb{R}^2 \setminus \Omega}. \quad (12)$$

In other words, a pair (Ω, ϵ) is *admissible* if ϵ is equal to a preassigned constant value $\hat{\epsilon}$ inside of Ω , and equal to the preassigned *background permittivity* ϵ_b outside of Ω . The domain Ω is called the *scattering domain*.

Remark 3.1 *For an admissible pair (Ω, ϵ) , and for given $\hat{\epsilon}$, ϵ_b , the permittivity ϵ is uniquely determined by Ω .*

With this definition, we can now formulate the *shape reconstruction problem*.

Shape reconstruction problem. Let us assume that we are given a constant $\hat{\epsilon} > 0$, a bounded function $\epsilon_b : \mathbb{R}^2 \rightarrow \mathbb{R}$, and some data \tilde{G} as in (10). Find a domain $\tilde{\Omega}$ such that the admissible pair $(\tilde{\Omega}, \tilde{\epsilon})$ reproduces the data, i.e. (9) holds with \tilde{u}_{jk} given by (6) for $j = 1, \dots, p$, $k = 1, \dots, K$.

Using the same notation and assumptions as in definition 3.1, we want to formulate another inverse problem which we will call the *inverse scattering problem* and which will play an important part when solving the shape reconstruction problem.

Inverse Scattering Problem. Let us assume that we are given a bounded function $\epsilon_b : \mathbb{R}^2 \rightarrow \mathbb{R}$, and some data \tilde{G} as in (10). Find a bounded function $\tilde{\epsilon}_s : \mathbb{R}^2 \rightarrow \mathbb{R}$ with $\text{supp}(\epsilon_s) \subset\subset B_r(0)$ such that $\tilde{\epsilon} = \epsilon_b + \tilde{\epsilon}_s$ reproduces the data, i.e. (9) holds with \tilde{u}_{jk} given by (6) for $j = 1, \dots, p$, $k = 1, \dots, K$.

The inverse scattering problem gives rise to the following decomposition of ϵ in \mathbb{R}^2 .

Decomposition of $\epsilon(x)$:

$$(i) \quad \epsilon = \epsilon_b + \epsilon_s \quad \text{in } \mathbb{R}^2 \quad (13)$$

$$(ii) \quad \text{supp}(\epsilon_s) \subset\subset B_r(0). \quad (14)$$

In other words, the permittivity distribution ϵ is decomposed into the background distribution ϵ_b and the perturbation ϵ_s which is assumed to have compact support and which we will refer to as the *scattering potential* in the following.

Solving the shape reconstruction problem requires only to find the *shape* of the domain $\tilde{\Omega}$, since the function $\tilde{\epsilon}$ is then uniquely determined by (12). Solving the inverse scattering problem, on the other hand, amounts to finding the entire function $\tilde{\epsilon}_s$ from the given data, which is much harder to do. However, it will turn out that finding a good *approximate* solution of the inverse scattering problem is much easier to achieve and will provide us with an excellent initial guess for starting our shape reconstruction routine.

Definition 3.1 allows us to formulate a first version of the strategy which we want to use for solving the shape reconstruction problem.

Strategy for solving the shape reconstruction problem. Construct a series of admissible pairs $(\Omega^{(n)}, \epsilon^{(n)})$, $n = 0, 1, 2, \dots$, such that the misfit between the data (10) and the calculated data corresponding to $(\Omega^{(n)}, \epsilon^{(n)})$ decreases with increasing n , and ideally, i.e. in absence of noise, tends to zero in the limit $n \rightarrow \infty$. Use the *approximate* solution of the inverse scattering problem (i),(ii) to initialize this series by determining a good starting element $(\Omega^{(0)}, \epsilon^{(0)})$.

3.2 The domains $\Omega^{(n)}$

In our numerical examples, each of the domains $\Omega^{(n)}$ which we are looking for can be given as a collection of a finite number L_n of disjoint, compact subdomains $\Omega_l^{(n)}$,

$l = 1, \dots, L_n$, with

$$\Omega^{(n)} = \bigcup_{l=1}^{L_n} \Omega_l^{(n)}, \quad \Omega_l^{(n)} \cap \Omega_{l'}^{(n)} = \emptyset \quad \text{for } l \neq l'. \quad (15)$$

The shapes of these subdomains $\Omega_l^{(n)}$ can in principle be arbitrary. In particular, they are allowed to be multiply connected, and to enclose some 'cavities' or 'holes' filled with background material. Moreover, the number L_n of these subdomains might (and usually does) vary with the iteration number n . For the derivation of the inversion method, we assume that the boundaries $\partial\Omega_l^{(n)}$ of these domains are sufficiently smooth (e.g. C^1).

It is essential for the success and the efficiency of the reconstruction scheme to have a good and flexible way of keeping track of the shape evolution during the reconstruction process. The method we have chosen in our reconstruction algorithm is a *level set representation* of the shapes as it was suggested by Santosa [40]. This representation has the advantage that the level set functions, which are in principle only used for *representing* the shapes, can in a natural way be made part of the reconstruction scheme itself. Doing so, it is not necessary anymore to refer to the shapes of the domains until the reconstruction process is completed. The *final* shape is then recovered from the representing level set function easily. In the following we will discuss in a more formal way how this can be achieved.

3.3 Level set representation of the domains $\Omega^{(n)}$

Assume that we are given a domain $\Omega \subset\subset B_r(0)$. The characteristic function $\chi_\Omega : \mathbb{R}^2 \rightarrow \{0, 1\}$ is defined in the usual way as

$$\chi_\Omega(x) = \begin{cases} 1 & , \quad x \in \Omega \\ 0 & , \quad x \in \mathbb{R}^2 \setminus \Omega. \end{cases} \quad (16)$$

Definition 3.2 We call a function $\phi : \mathbb{R}^2 \rightarrow \mathbb{R}$ a level set representation of Ω if

$$\chi_\Omega(x) = \Psi_\phi(x) \quad \text{on } \mathbb{R}^2 \quad (17)$$

where $\Psi_\phi : \mathbb{R}^2 \rightarrow \{0, 1\}$ is defined as

$$\Psi_\phi(x) = \begin{cases} 1 & , \quad \phi(x) \leq 0 \\ 0 & , \quad \phi(x) > 0. \end{cases} \quad (18)$$

For each function $\phi : \mathbb{R}^2 \rightarrow \mathbb{R}$ there is a domain Ω associated with ϕ by (17),(18) which we call $\Omega[\phi]$. It is clear that different functions ϕ_1, ϕ_2 , $\phi_1 \neq \phi_2$, can be associated with the same domain $\Omega[\phi_1] = \Omega[\phi_2]$, but that different domains cannot have

the same level set representation. Therefore, we can use the level set representation for unambiguously specifying a domain Ω by any one of its associated level set functions.

The boundary $\Gamma = \partial\Omega[\phi]$ of a domain $\Omega[\phi]$, represented by the level set function ϕ , is defined as

$$\begin{aligned} \Gamma = \{x \in \mathbb{R}^2 : \quad & \text{for all } \epsilon > 0 \text{ we can find } x_1, x_2 \in B_\epsilon(x) \\ & \text{with } \phi(x_1) > 0 \text{ and } \phi(x_2) < 0\} \end{aligned} \quad (19)$$

Definition 3.3 We call a triple (Ω, ϵ, ϕ) , which consists of a domain $\Omega \subset\subset B_r(0)$ and bounded functions $\epsilon, \phi : \mathbb{R}^2 \rightarrow \mathbb{R}$, admissible if the pair (Ω, ϵ) is admissible in the sense of definition 3.1, and ϕ is a valid level set representation of Ω .

Remark 3.2 For an admissible triple (Ω, ϵ, ϕ) , and for given $\hat{\epsilon}, \epsilon_b$, the pair (Ω, ϵ) is uniquely determined by ϕ .

We use these definitions to reformulate our shape reconstruction problem.

Level set formulation of the shape reconstruction problem. Given a constant $\hat{\epsilon} > 0$, a background distribution ϵ_b , and some data \tilde{G} as in (10). Find a level set function $\tilde{\phi}$ such that the corresponding admissible triple $(\tilde{\Omega}, \tilde{\epsilon}, \tilde{\phi})$ reproduces the data, i.e. (9) holds with \tilde{u}_{jk} given by (6) for $j = 1, \dots, p$, $k = 1, \dots, K$.

The strategy for solving this shape reconstruction problem has to be reformulated, too. It reads now as follows.

Strategy for solving the reformulated shape reconstruction problem. Construct a series of admissible triples $(\Omega^{(n)}, \epsilon^{(n)}, \phi^{(n)})$, $n = 0, 1, 2, \dots$, such that the misfit between the data (10) and the calculated data corresponding to $(\Omega^{(n)}, \epsilon^{(n)}, \phi^{(n)})$ decreases with increasing n , and ideally, i.e. in absence of noise, tends to zero in the limit $n \rightarrow \infty$. For finding this series we only have to keep track of $\epsilon^{(n)}$ and $\phi^{(n)}$, but not of $\Omega^{(n)}$. The function $\epsilon^{(n)}$ is needed in each step for solving a forward problem (1), and a corresponding adjoint problem. The knowledge of $\phi^{(n)}$ is used in each step to determine $\epsilon^{(n)}$. The final level set function $\phi^{(N)}$, which satisfies some stopping criterion, is used to recover the final shape $\Omega^{(N)}$ via (17).

4 Step 2: Solving the shape reconstruction problem

In this section we derive the basic shape reconstruction method which uses adjoint fields and the level set representation introduced above. The initializing procedure ('Step 1') for this reconstruction routine will be discussed in section 5.

4.1 Function spaces

We want to specify now the function spaces which we will be working with. The main objective of this section is to introduce the inner products on these function spaces, which will become important when defining the adjoint linearized operators in sections 4.6 and 5.3.

The space of sources and scattering sources Y is defined as

$$Y = \left\{ q : \mathbb{R}^2 \rightarrow \mathbb{C}, \quad q = 0 \text{ on } \mathbb{R}^2 \setminus B_r(0), \quad \int_{B_r(0)} |q|^2 dx < \infty \right\}, \quad (20)$$

$$\langle q_1, q_2 \rangle_Y = \int_{B_r(0)} q_1(x) \overline{q_2(x)} dx, \quad (21)$$

where the bar means 'complex conjugate'. The space F of scattering potentials is defined as

$$F = \left\{ \epsilon_s : \mathbb{R}^2 \rightarrow \mathbb{R}, \quad \epsilon_s = 0 \text{ on } \mathbb{R}^2 \setminus B_r(0), \quad \int_{B_r(0)} |\epsilon_s|^2 dx < \infty \right\}, \quad (22)$$

$$\langle \epsilon_{s,1}, \epsilon_{s,2} \rangle_F = \int_{B_r(0)} \gamma \epsilon_{s,1}(x) \epsilon_{s,2}(x) dx, \quad (23)$$

with some positive weighting factor $\gamma > 0$ which is introduced here for convenience. Analogously, the space of level set functions Φ is defined as

$$\Phi = \left\{ \phi : \mathbb{R}^2 \rightarrow \mathbb{R}, \quad \phi = 0 \text{ on } \mathbb{R}^2 \setminus B_r(0), \quad \int_{B_r(0)} |\phi|^2 dx < \infty \right\}, \quad (24)$$

$$\langle \phi_1, \phi_2 \rangle_\Phi = \int_{B_r(0)} \gamma \phi_1(x) \phi_2(x) dx. \quad (25)$$

This space for the level set functions is mainly chosen in order to have an inner product available which is convenient for the derivation of the shape reconstruction algorithm. We mention that the regularity of an arbitrary function in Φ is, strictly speaking, not sufficient for our purposes, such that we will apply further regularity constraints on those level set functions $\phi \in \Phi$ which we choose for representing the boundaries $\partial\Omega[\phi]$.

The data space Z_j corresponding to source q_j , $j = 1, \dots, p$, was already introduced earlier, and is given by $Z_j = \mathbb{C}^{D_j}$, where D_j is the total number of receivers corresponding to source q_j .

4.2 Operators

In the following, we will introduce some operators which will enable us to formulate the shape reconstruction problem in a way suitable for deriving the inversion algorithm.

Given a constant $\hat{\epsilon}$ and a bounded function $\epsilon_b : \mathbb{R}^2 \rightarrow \mathbb{R}$. Then, with each level set function $\phi \in \Phi$ a uniquely determined scattering potential $\Lambda(\phi)$ is associated by putting

$$\Lambda(\phi)(x) = \begin{cases} \hat{\epsilon} - \epsilon_b(x) & , \quad \phi(x) \leq 0 \\ 0 & , \quad \phi(x) > 0. \end{cases} \quad (26)$$

With (18) we can write this also as

$$\Lambda(\phi)(x) = \Psi_\phi(x)(\hat{\epsilon} - \epsilon_b(x)) \quad , \quad x \in \mathbb{R}^2. \quad (27)$$

Notice that the operator Λ is chosen such that the triple (Ω, ϵ, ϕ) with $\epsilon = \epsilon_b + \Lambda(\phi)$ and domain $\Omega[\phi]$ forms an admissible triple (Ω, ϵ, ϕ) in the sense of definition 3.3. Moreover, for (Ω, ϵ, ϕ) an admissible triple, we see that $\Lambda(\phi)$ is just the scattering potential ϵ_s as defined in (13),(14)

$$\Lambda(\phi)(x) = \epsilon_s(x) = \chi_\Omega(x)(\hat{\epsilon} - \epsilon_b(x)) \quad , \quad x \in \mathbb{R}^2. \quad (28)$$

Let us assume now that we are given a background permittivity ϵ_b and that we have collected some data \tilde{G}_{jk} which correspond to the 'true' permittivity distribution

$$\tilde{\epsilon} = \epsilon_b + \tilde{\epsilon}_s, \quad (29)$$

where $\tilde{\epsilon}_s$ is the 'true' scattering potential. The *residual operators* R_{jk} map for a source position q_j and a frequency f_k a given scattering potential ϵ_s to the corresponding mismatch in the data

$$R_{jk} : F \longrightarrow Z_j \quad , \quad R_{jk}(\epsilon_s) = M_j u_{jk} - \tilde{G}_{jk} \quad (30)$$

where u_{jk} solves

$$\Delta u_{jk} + [a_k(\epsilon_b + \epsilon_s)(x) + ib\sigma(x)] u_{jk} = q_j \quad (31)$$

and M_j is the measurement operator defined in (8). From (9) we see that for the 'true' scattering potential the residuals vanish,

$$R_{jk}(\tilde{\epsilon}_s) = 0 \quad \text{for } j = 1, \dots, p, \quad k = 1, \dots, K, \quad (32)$$

if the data are noise-free.

The *forward operators* T_{jk} which map a given level set function $\phi \in \Phi$ into the corresponding mismatch in the data are defined by

$$T_{jk} : \Phi \longrightarrow Z_j \quad , \quad T_{jk}(\phi) = R_{jk}(\Lambda(\phi)) \quad (33)$$

for $j = 1, \dots, p, \quad k = 1, \dots, K$. The goal is to find a level set function $\tilde{\phi} \in \Phi$ such that

$$T_{jk}(\tilde{\phi}) = 0 \quad \text{for } j = 1, \dots, p, \quad k = 1, \dots, K. \quad (34)$$

We mention that all three operators Λ , R_{jk} and T_{jk} are nonlinear.

4.3 Linearized operators

For the derivation of the shape reconstruction algorithm, we will need expressions for the linearized operators corresponding to the nonlinear operators introduced above, and for their adjoints with respect to the given inner products. In this section, we define the linearized operators, and expressions for their adjoints are derived in section 4.6.

In Santosa [40] it is shown that, for a homogeneous background ϵ_b , the infinitesimal response $\delta\epsilon_s(x)$ in the scattering potential $\epsilon_s(x)$ to an infinitesimal change $\delta\phi(x)$ of the level set function $\phi(x)$ has the form

$$\delta\epsilon_s(x) = - [\hat{\epsilon} - \epsilon_b] \frac{\delta\phi(x)}{|\nabla\phi(x)|} \Big|_{x \in \partial\Omega[\phi]}. \quad (35)$$

The function $\delta\epsilon_s$ in (35) can be interpreted as a 'surface measure' on the boundary $\Gamma = \partial\Omega[\phi]$. Similar to (35), we would like to define the linearized operator $\tilde{\Lambda}'[\phi]$ by

$$\left(\tilde{\Lambda}'[\phi] \delta\phi \right) (x) = - [\hat{\epsilon} - \epsilon_b(x)] \frac{\delta\phi(x)}{|\nabla\phi(x)|} \hat{\delta}_\Gamma(x) \quad (36)$$

where $\hat{\delta}_\Gamma(x)$ denotes the Dirac delta distribution concentrated on $\Gamma = \partial\Omega[\phi]$. In this interpretation, (36) describes an infinitesimal 'surface load' of permittivity on Γ which has to be recovered from the mismatch in the data.

However, the expression on the right hand side of (36) is not an element of F which causes problems when we want to calculate the inner products defined in section 4.1. Therefore, we will introduce an approximation to the operator (36) which maps from Φ into F and which will be more convenient for the derivation of the reconstruction method.

For a given level set function $\phi \in \Phi$, let $\Gamma = \partial\Omega[\phi]$ and $B_\rho(\Gamma) = \cup_{y \in \Gamma} B_\rho(y)$ a small neighborhood of Γ with some given constant $0 < \rho \ll 1$. The (approximated) linearized operator $\Lambda'[\phi]$ is defined as

$$\Lambda'[\phi] : \Phi \longrightarrow F, \quad (\Lambda'[\phi] \delta\phi) (x) = - [\hat{\epsilon} - \epsilon_b(x)] \frac{\delta\phi(x)}{|\nabla\phi(x)|} C_\rho(\Gamma) \chi_{B_\rho(\Gamma)}(x). \quad (37)$$

Here, $C_\rho(\Gamma) = L(\Gamma)/\text{Vol}(B_\rho(\Gamma))$ where $L(\Gamma) = \int_{B_r(0)} \hat{\delta}_\Gamma(x) dx$ is the length of the boundary Γ , and $\text{Vol}(B_\rho(\Gamma)) = \int_{B_r(0)} \chi_{B_\rho(\Gamma)}(x) dx$ is the volume of $B_\rho(\Gamma)$. For a very small ρ we will get a very large weight $C_\rho(\Gamma)$, whereas for increasing ρ this weight $C_\rho(\Gamma)$ decreases accordingly. The operator defined in (37) maps now from Φ into F such that we can make use of the inner products defined on these spaces.

We mention that the term $|\nabla\phi(x)|$ in (35), (36), as well as the derivation of these expressions, implies some regularity constraint on ϕ . For example, $\phi \in C^1$ would be possible. Another possibility would be to use a 'signed distance function'

as a standard representation of the boundary [42]. We do not want to specify the regularity of ϕ at this point, but assume instead that it is 'sufficiently smooth' for our purposes.

The linearized residual operator $R'_{jk}[\epsilon_s]$ is defined by

$$R'_{jk}[\epsilon_s] : F \longrightarrow Z_j \quad , \quad R'_{jk}[\epsilon_s]\delta\epsilon_s = M_j v_{jk} \quad (38)$$

where v_{jk} solves the linearized equation

$$\Delta v_{jk} + [a_k(\epsilon_b + \epsilon_s)(x) + ib\sigma(x)] v_{jk} = -a_k \delta\epsilon_s(x) u_{jk}(x) \quad (39)$$

with u_{jk} a solution of (31). This representation can be derived by perturbing

$$\epsilon_s \rightarrow \epsilon_s + \delta\epsilon_s \quad , \quad u_{jk} \rightarrow u_{jk} + v_{jk}, \quad (40)$$

plugging this into (31) and neglecting terms which are of higher than linear order in the perturbations $\delta\epsilon_s, v_{jk}$.

Notice that the right hand side of (39) can be interpreted as a 'scattering source'. We will use this concept later for solving our inverse scattering problem approximately in order to find a starting guess for the shape reconstruction scheme. But we want to mention here already that the linearization assumption built into (38), (39), namely that v_{jk} is small compared to u_{jk} , will not be necessary when solving the inverse scattering problem. That will allow us to circumvent some difficulties which often arise in high contrast inverse problems due to the occurrence of strong nonlinearities.

As our third linearized operator, we introduce the linearized forward operator $T'_{jk}[\phi]$ by putting

$$T'_{jk}[\phi] : \Phi \longrightarrow Z_j \quad , \quad T'_{jk}[\phi]\delta\phi = R'_{jk}[\Lambda(\phi)] \Lambda'[\phi]\delta\phi. \quad (41)$$

All three operators $\Lambda'[\phi]$, $R'_{jk}[\epsilon_s]$, and $T'_{jk}[\phi]$ are linear.

4.4 A nonlinear Kaczmarz-type approach

The algorithm works in a 'single-step fashion' as follows. Instead of using the data (10) for all sources and all frequencies simultaneously, we only use the data for one source and frequency at a time while updating the linearized residual operator after each determination of the corresponding incremental correction $\delta\phi$. So, in each step we will look for a solution of the equation

$$T'_{jk}[\phi]\delta\phi_{jk} = -T_{jk}(\phi) \quad (42)$$

for a given source index $j = 1, \dots, p$ and a given frequency index $k = 1, \dots, K$. After correcting ϕ by

$$\phi \longrightarrow \phi + \delta\phi_{jk}, \quad (43)$$

we use the updated residual equation (42) to compute the next correction $\delta\phi_{j'k'}$. Doing this for one equation after the other, until each of the sources q_j and each of the frequencies f_k has been considered exactly once, will yield one complete sweep of the algorithm. This procedure is similar to the Kaczmarz method for solving linear systems, or the algebraic reconstruction technique (ART) in x-ray tomography [32] and the simultaneous iterative reconstruction technique (SIRT) as presented in [16]. Related approaches have also been employed in ultrasound tomography by Natterer and Wübbeling [33], in more general bilinear inverse problems by Natterer [34], in optical tomography by Dorn [17], and in 3D-electromagnetic induction tomography (EMIT) by Dorn *et alii* [18].

4.5 The minimization problem

Let us assume now that we are given a level set function $\phi^{(n)}(x)$ and a scattering potential $\epsilon_s^{(n)}(x)$ such that $(\Omega^{(n)}, \epsilon_b + \epsilon_s^{(n)}, \phi^{(n)})$ forms an admissible triple in the sense of definition 3.3. Using a data set \tilde{G}_{jk} corresponding to the fixed source position q_j and the frequency f_k , we want to find an update $\delta\phi^{(n)}$ to $\phi^{(n)}$ such that for the admissible triple

$$\begin{aligned} & \left(\Omega^{(n+1)}, \epsilon_b + \epsilon_s^{(n+1)}, \phi^{(n+1)} \right) := \\ & \left(\Omega[\phi^{(n)} + \delta\phi^{(n)}], \epsilon_b + \Lambda(\phi^{(n)} + \delta\phi^{(n)}), \phi^{(n)} + \delta\phi^{(n)} \right) \end{aligned} \quad (44)$$

the residuals in the data corresponding to this source and this frequency vanish

$$T_{jk}(\phi^{(n+1)}) = T_{jk}(\phi^{(n)} + \delta\phi^{(n)}) = 0. \quad (45)$$

Applying a Newton-type approach, we get from (45) a correction $\delta\phi^{(n)}$ for $\phi^{(n)}$ by solving

$$T'_{jk}[\phi^{(n)}]\delta\phi^{(n)} = -T_{jk}(\phi^{(n)}) = -\left(M_j u_{jk} - \tilde{G}_{jk}\right) \quad (46)$$

where u_{jk} satisfies (31) with $\epsilon_s = \Lambda(\phi^{(n)})$

$$\Delta u_{jk} + \left[a_k(\epsilon_b + \Lambda(\phi^{(n)}))(x) + ib\sigma(x) \right] u_{jk} = q_j(x) \quad (47)$$

and

$$\epsilon_b(x) + \Lambda(\phi^{(n)})(x) = \begin{cases} \hat{\epsilon} & , \quad x \in \Omega[\phi^{(n)}] \\ \epsilon_b(x) & , \quad x \in \mathbb{R}^2 \setminus \Omega[\phi^{(n)}]. \end{cases} \quad (48)$$

Since we have only few data given for one source and one frequency, equation (46) usually will have many solutions (in the absence of noise), such that we have to pick

one according to some criterion. We choose to take that solution which minimizes the energy norm of $\delta\phi^{(n)}$

$$\text{Min } \|\delta\phi^{(n)}\|_2 \quad \text{subject to} \quad T'_{jk}(\phi^{(n)})\delta\phi^{(n)} = -\left(M_j u_{jk} - \tilde{G}_{jk}\right). \quad (49)$$

This solution can be formulated explicitly. It is

$$\delta\phi_{\text{MN}}^{(n)} = -T'_{jk}[\phi^{(n)}]^* \left(T'_{jk}[\phi^{(n)}]T'_{jk}[\phi^{(n)}]^*\right)^{-1} \left(M_j u_{jk} - \tilde{G}_{jk}\right), \quad (50)$$

where $T'_{jk}[\phi^{(n)}]^*$ denotes the adjoint operator to $T'_{jk}[\phi^{(n)}]$.

4.6 The adjoint linearized operators

In order to calculate the minimal norm solution (50), we will need practically useful expressions for the adjoints of the linearized operators of section (4.3). We will present such expressions in this section. The calculation of the actions of these operators will typically require to solve an adjoint Helmholtz problem. This explains the name 'adjoint field method' of the inversion method employed here.

To start with, a simple calculation gives us the following theorem.

Theorem 4.1 *The adjoint operator $\Lambda'[\phi]^*$ which corresponds to the linearized operator $\Lambda'[\phi]$ is given by*

$$\Lambda'[\phi]^* : F \longrightarrow \Phi \quad , \quad (\Lambda'[\phi]^* \delta\epsilon_s)(x) = -[\hat{\epsilon} - \epsilon_b(x)] \frac{\delta\epsilon_s(x)}{|\nabla\phi(x)|} C_\rho(\Gamma) \chi_{B_\rho(\Gamma)}(x). \quad (51)$$

The next theorem describes the adjoint operator $R'_{jk}[\epsilon_s]^*$ which corresponds to $R'_{jk}[\epsilon_s]$. Its proof is analogous to the proof of Theorem 4.1 in the appendix, or to the proof given in a similar situation in Dorn *et al.* [18], and is therefore omitted here.

Theorem 4.2 *Let $\zeta = (\zeta_1, \dots, \zeta_{D_j})^T \in Z_j$ and let x_{jd} , $d = 1, \dots, D_j$ be the detector positions corresponding to q_j . Then the action of the adjoint operator $R'_{jk}[\epsilon_s]^*$ on ζ is given by*

$$R'_{jk}[\epsilon_s]^* \zeta = -\frac{1}{a_k} \mathcal{R}e(\overline{u_{jk} z_{jk}}) \chi_{B_r(0)} \quad (52)$$

where u_{jk} solves

$$\Delta u_{jk} + \kappa_k(x) u_{jk} = q_j(x), \quad (53)$$

and z_{jk} solves the 'adjoint equation'

$$\Delta z_{jk} + \kappa_k(x) z_{jk} = \sum_{d=1}^{D_j} \bar{\zeta}_d \delta(x - x_{jd}) \quad (54)$$

with

$$\kappa_k(x) = a_k[\epsilon_b(x) + \epsilon_s(x)] + ib_k \sigma(x) \quad (55)$$

and a_k, b_k defined as in (7).

Finally, by combining theorems 4.1 and 4.2, we get an expression for the adjoint operator $T'_{jk}[\phi]^*$ which corresponds to the linearized forward operator $T'_{jk}[\phi]$. It is described in the following theorem.

Theorem 4.3 *Let $\zeta = (\zeta_1, \dots, \zeta_{D_j})^T \in Z_j$ and let x_{jd} , $d = 1, \dots, D_j$ be the detector positions corresponding to q_j . Then the adjoint operator $T'_{jk}[\epsilon_s]^*$ acts on ζ in the following way*

$$\begin{aligned} T'_{jk}[\phi]^* \zeta &= \Lambda'[\phi]^* R'_{jk}[\Lambda(\phi)]^* \zeta \\ &= \frac{[\hat{\epsilon} - \epsilon_b(x)]}{a_k |\nabla \phi(x)|} \mathcal{R}e(\overline{u_{jk} z_{jk}}) C_\rho(\Gamma) \chi_{B_\rho(\Gamma)}(x), \end{aligned} \quad (56)$$

where u_{jk} solves (53) and z_{jk} solves (54) with ϵ_s replaced by $\Lambda(\phi)$.

4.7 The operators $T'_{jk} T'^*_{jk}$

Let us consider the operator

$$C_{jk}^{(n)} := T'_{jk}[\phi^{(n)}] T'^*_{jk}[\phi^{(n)}] \quad (57)$$

in (50) more closely. Using (41) it gets the form

$$C_{jk}^{(n)} = R'_{jk}[\Lambda(\phi^{(n)})] \Lambda'[\phi^{(n)}] \Lambda'[\phi^{(n)}]^* R'_{jk}[\Lambda(\phi^{(n)})]^*. \quad (58)$$

With (37), (51) we see that, due to the operator $\Lambda'[\phi^{(n)}] \Lambda'[\phi^{(n)}]^*$ in (58), $C_{jk}^{(n)}$ maps first from the data space to functions in F or Φ which are supported on $B_\rho(\Gamma)$, and then back to the data space. In a discretized setting, it might happen that for a coarse mesh (and a small ρ) the number of pixels representing $B_\rho(\Gamma)$ becomes close to (or even smaller than) the number of data points. This observation lets us expect that the inversion of $C_{jk}^{(n)}$ in (50) will be highly ill-conditioned and unstable. This is confirmed by our numerical experiments so far.

Therefore, we will regularize the inversion of $C_{jk}^{(n)}$ and the action of its inverse on the right hand side of (46).

4.8 Regularization of $T'_{jk} T'^*_{jk}$

A standard way of regularization is the Tychonov-Phillips regularization scheme which amounts to replacing the operator $T'_{jk}[\phi^{(n)}] T'^*_{jk}[\phi^{(n)}]$ in (50) by the operator

$$T'_{jk}[\phi^{(n)}] T'^*_{jk}[\phi^{(n)}] + \lambda I \quad (59)$$

with some suitably chosen regularization parameter $\lambda > 0$. A small λ means little regularization, whereas in the case of very noisy data we might wish to use a very

large λ such that (59) is dominated by the term λI and we can approximate it further by a simple multiplication with the regularization parameter λ .

However, motivated by the above mentioned observations, we choose a different form of regularization. First, we add a Tychonov-Phillips term to $\Lambda'[\phi^{(n)}] \Lambda'[\phi^{(n)}]^*$ such that the right hand side of (58) becomes

$$C_{jk}^{(n)} \approx R'_{jk}[\Lambda(\phi^{(n)})] \left(\Lambda'[\phi^{(n)}] \Lambda'[\phi^{(n)}]^* + \lambda I \right) R'_{jk}[\Lambda(\phi^{(n)})]^*. \quad (60)$$

Now, using a very large regularization parameter λ , we approximate (60) further by

$$C_{jk}^{(n)} \approx \lambda R'_{jk}[\Lambda(\phi^{(n)})] R'_{jk}[\Lambda(\phi^{(n)})]^*. \quad (61)$$

Since calculating the operator (61) in each step of the inversion routine is still very time-consuming, we approximate this operator further by replacing the argument $\Lambda(\phi^{(n)})$ by the background scattering potential which is zero. Therefore, we end up with the following approximation for $C_{jk}^{(n)}$

$$C_{jk}^{(n)} \approx \hat{C}_{jk} := R'_{jk}[0] R'_{jk}[0]^* \quad \text{for all } n = 1, 2, \dots \quad (62)$$

The multiplier λ is neglected in (62) since it becomes part of the relaxation parameter in our inversion scheme. We see that we have replaced in (62) the highly ill-conditioned and difficult to calculate operator $C_{jk}^{(n)}$ by a much better conditioned operator \hat{C}_{jk} which has to be computed only once and which can be precalculated before starting the inversion routine.

The next theorem tells us how to practically compute the operator \hat{C}_{jk} for a given background permittivity ϵ_b .

Theorem 4.4 *Let us assume that we are given a background permittivity distribution ϵ_b , a finite set of sources q_j , $j = 1, \dots, p$, and for each of these sources a finite set of receiver positions x_{jd} , $d = 1, \dots, D_j$. We apply each of the sources with K different frequencies f_k , $k = 1, \dots, K$. The operators \hat{C}_{jk} , $j = 1, \dots, p$, $k = 1, \dots, K$, are then described by $D_j \times D_j$ matrices of the form*

$$\hat{C}_{jk} = \left\{ \int_{B_r(0)} \overline{u_{jk}(x) \varphi_{dk}(x)} u_{jk}(x) \varphi_{lk}(x) \right\}_{\substack{l=1, \dots, D_j \\ d=1, \dots, D_j}}, \quad (63)$$

where $\varphi_{\nu k}$ solves

$$\Delta \varphi_{\nu k} + (a_k \epsilon_b + i b_k \sigma) \varphi_{\nu k} = \delta(x - x_{j\nu}) \quad (64)$$

and u_{jk} solves

$$\Delta u_{jk} + (a_k \epsilon_b + i b_k \sigma) u_{jk} = q_j. \quad (65)$$

The index ν in (64) can stand for a receiver index d or l . In (63), the receiver index l is the row index, and the receiver index d is the column index of \hat{C}_{jk} .

The proof of this theorem is similar to the proof of Theorem 5.2 given in the appendix such that we omit it here.

4.9 Updating the level set function

In order to calculate a correction $\delta\phi_{\text{MN}}^{(n)}$ by (50) we have to apply the operator $T'_{jk}[\phi^{(n)}]^*$ to the vector

$$\zeta := \hat{C}_{jk}^{-1} \left(M_j u_{jk} - \tilde{G}_{jk} \right). \quad (66)$$

An explicit formula for $T'_{jk}[\phi^{(n)}]$ was already given in (56)

$$T'_{jk}[\phi^{(n)}]^* \zeta = \frac{[\hat{\epsilon} - \epsilon_b(x)]}{a_k |\nabla \phi^{(n)}(x)|} \mathcal{R}e \left(\overline{u_{jk}(x) z_{jk}(x)} \right) C_\rho(\Gamma) \chi_{B_\rho(\Gamma)}(x), \quad (67)$$

where u_{jk} and z_{jk} solve (53)- (55) with ϵ_s replaced by $\Lambda(\phi^{(n)})$.

To stabilize the reconstruction scheme, we replace the term $|\nabla \phi(x)|$ in (67) by some constant c_1 . Doing so we avoid dividing by numerical derivatives which might cause instabilities due to numerical noise and roundoff errors. This is justified as long as $|\nabla \phi(x)|$ does not vary too much along the boundary. It turns out that the updates we apply in our numerical examples to the level set functions usually justify this assumption. In cases with limited view and very noisy data, however, we will apply an additional 'smoothing procedure' (which is described in section 4.10) to the level set functions near the boundary after each update in order to guarantee the necessary regularity for the succeeding steps.

With these modifications, (50) yields the following *update formula for the level set function*

$$\delta\hat{\phi}^{(n)}(x) = - \frac{\hat{\epsilon} - \epsilon_b(x)}{c_1 a_k} \mathcal{R}e \left(\overline{u_{jk}(x) z_{jk}(x)} \right) C_\rho(\Gamma) \chi_{B_\rho(\Gamma)}(x) \quad (68)$$

where u_{jk} and z_{jk} solve (53)- (55) with ζ given by (66) and ϵ_s replaced by $\Lambda(\phi^{(n)})$.

Notice that, although we did not explicitly impose any regularity constraints on the updates (68), they are in the range of $R'_{jk}[\Lambda(\phi^{(n)})]^*$ (up to the factor $\hat{\epsilon} - \epsilon_b(x)$) which implicitly gives us some information about the regularity we can expect. Our numerical experiments so far indicate that the degree of regularity which is achieved by applying (68) is typically sufficient 'for practical purposes' in those situations where the data are not too noisy and where we have suitably arranged receiver positions all around the obstacles. (This is the 'full view' situation.)

However, in cases of noisy and limited-view data, the resulting boundaries look rough and fuzzy, in particular when high-frequency data are used for the reconstruction. In these situations, we can improve the results by applying some additional regularization on ϕ . A possible way of doing so is to filter the level set function after

each update in order to smooth it locally. An example for such a procedure is 'curve shortening by diffusion', which is briefly described at the end of section 4.10.

We mention that an interesting (and from a mathematical point of view more satisfactory) alternative to this procedure would be to apply some additional regularity constraints already in the derivation of (68), such that we would not have to worry at all about the smoothness of the resulting level set functions. We will investigate possible ways of doing so in our future research.

4.10 Implementation: The levelART algorithm

In brief algorithmic form, the nonlinear Kaczmarz-type method for shape reconstruction using level sets (which we call for short 'levelART' because of its above mentioned similarity to the 'ART' algorithm in x-ray tomography) can be written in the following way.

Preparation step.

- Calculate \hat{C}_{jk} and

$$D_{jk} = \hat{C}_{jk}^{-1} \quad (69)$$

according to (63) for each source q_j , $j = 1, \dots, p$, and each frequency f_k , $k = 1, \dots, K$, and store in memory for later use.

- Build groups of frequencies $G_m = \{f_1, \dots, f_{K_m}\}$, $m = 1, \dots, M$.

Initialization.

$n = 0$;

$(\Omega^{(0)}, \epsilon^{(0)}, \phi^{(0)})$ given from STAF.

Reconstruction loop.

```

FOR  $m = 1 : M$       march over frequency groups  $G_m$ 
  FOR  $i = 1 : I_m$     perform  $I_m$  sweeps for frequency group  $G_m$ 
    FOR  $k = 1 : K_m$   march over frequencies in  $G_m$ 
      FOR  $j = 1 : p$    march over sources  $q_j$  for each frequency
         $\zeta_{jk} = D_{jk}(M_j u_{jk} - \tilde{G}_{jk})$ ;  $u_{jk}$  solves (53) with  $\epsilon^{(n)}$ 
         $\delta\phi_{jk} = -\frac{\hat{\epsilon} - \epsilon_b(x)}{a_k} \mathcal{R}e(\overline{u_{jk} z_{jk}}) \chi_{B_\rho(\Gamma)}$ ;  $z_{jk}$  solves (54) with  $\epsilon^{(n)}$  and  $\zeta_{jk}$ 
      END
       $\delta\phi^{(n)}(x) = \sum_{j=1}^p \delta\phi_{jk}(x)$ ;
       $\phi^{(n+1)} = C_{LS}^{(n)}(\phi^{(n)} + \eta \frac{C_\rho(\Gamma)}{c_1} \delta\phi^{(n)})$ ;      update level set function
      Optional step: 'curve shortening' by diffusion. See separate chart.
       $\epsilon^{(n+1)} = \epsilon_b + \Lambda(\phi^{(n+1)})$ ;  $n = n + 1$ ;      Reinitialization  $n \rightarrow n + 1$ 
    END
  END
  alternatively, some stopping criteria can be used here
END
END
 $(\Omega^{(N)}, \epsilon^{(N)}, \phi^{(N)}) = (\Omega[\phi^{(n)}], \epsilon_b + \Lambda(\phi^{(n)}), \phi^{(n)})$ ;      Final reconstruction.

```

Here, η is a relaxation parameter for the update of the level set function which is determined empirically. The constant $C_\rho(\Gamma)$ could be calculated explicitly for the actual curve $\Gamma^{(n)}$, or it could be approximated by some value corresponding to a simple geometrical object (to give an example, in case of a single circle it would be $C_\rho(\Gamma) = (2\rho)^{-1}$). In our numerical experiments so far, however, it is simply considered as part of η . The same holds true for c_1 . The constant ρ is in our numerical experiments chosen between 30-40 cm, which corresponds to 2-3 grid cells. The scaling factor $C_{\text{LS}}^{(n)}$ is determined after each update to keep the global minimum (or maximum) of the level set function at a constant value.

The following smoothing filter on the level set function is optional. We usually apply it when we use noisy high-frequency data for the reconstruction. Especially in the limited-view examples presented in sections 6.3 and 6.4, the application of this filter improves the reconstructions significantly. Smoothing the level set function with this filter has the effect of local curve shortening. Roughness and small scale oscillations in the reconstructed boundaries are smoothed out such that the 'energy' of the reconstructed boundaries is reduced. The filtering step can be described as follows.

Optional step: 'Curve shortening' by diffusion.

Introduce artificial time $\tau \in \mathbb{R}$. $\frac{\partial}{\partial \tau}$ = time derivative, Δ = Laplace operator.

Solve initial value problem (with absorbing boundary conditions) on $B_r(0)$:

$$\begin{aligned}\tilde{\phi}(x, 0) &= \phi^{(n+1)}(x); \\ \frac{\partial}{\partial \tau} \tilde{\phi}(x, \tau) &= \Delta \tilde{\phi}(x, \tau), \quad \tau \in [0, T_\lambda], \quad x \in B_r(0). \\ \phi^{(n+1)}(x) &= \tilde{\phi}(x, T_\lambda),\end{aligned}$$

with regularization parameter T_λ .

5 Step 1: A Source-Type Adjoint Field method

For starting our shape reconstruction method using level sets we will need an initial guess $(\Omega^{(0)}, \epsilon^{(0)}, \phi^{(0)})$.

Although it is possible just to create an arbitrary initial guess without using any data at all, we believe that it is important for the efficiency and the robustness of such a method to start it with a *good* initial guess. There are several reasons for this. First, when deriving the shape reconstruction method (which we will call for short 'levelART' in the following) we used a perturbation approach which is strictly

justified only when we already have a good first guess available. Moreover, we see in our numerical experiments that starting with a good initial guess stabilizes the shape reconstruction routine, in particular in cases where the data are incomplete and noisy. In addition, finding a good first guess reduces the amount of work which has to be done by the levelART routine itself, such that in the end the combined code will converge much more rapidly than levelART alone would do without a good initialization.

In this section, we will present the second key point of our combined inversion scheme, namely a *fast*, *inexpensive* and *stable* method for finding a very good first guess $(\Omega^{(0)}, \epsilon^{(0)}, \phi^{(0)})$ for levelART. This method is designed to share basic features with the levelART algorithm, such that it can be implemented in addition to levelART with almost no extra cost.

5.1 Source-type methods

In the framework of inverse scattering problems, the method we propose here can be considered as a 'source-type inversion method'. Roughly speaking, the general idea of source-type reconstruction methods in inverse scattering is to split a given nonlinear inverse scattering problem into two subproblems. The first one is linear, and tries to recover a virtual 'equivalent source' in the medium which would be able to fit the data if applied with the known background distribution. This equivalent source is related to the unknown scattering potential by a nonlinear 'constitutive' relation. Therefore, in the second part of the algorithm, a nonlinear inverse problem has to be solved to derive the scattering potential from the recovered equivalent source distribution.

This idea is not at all new. It has been applied for example in the Source-Type Integral Equation (STIE) method of Habashy *et al* [21], or in the method presented by Chew *et al.* in [9]. More recently, similar ideas have been applied by Abdullah *et al.* [1], Caorsi *et al.* [6], and van den Berg *et al.* [46, 47].

All of these approaches have in common that they use the source-type method as a stand-alone inversion scheme. Such a method has the advantage that it is not as sensitive to strong nonlinearities in the inverse problem as for example perturbation methods or the Born or Rytov approximation are [15, 20, 27].

On the other hand, interpreting the inverse scattering problem as an inverse source problem is not without drawbacks. For example, the existence of so-called 'non-radiating sources' or 'invisible sources' gives rise to a nonuniqueness in the inverse source problem, which is difficult to deal with when solving the nonlinear part [1, 14, 21]. Moreover, it is not clear at all how to combine properly the information corresponding to different experiments, since each experiment creates its own 'equiv-

alent sources' and its own 'invisible sources'. For more information about possible applications, advantages and drawbacks of the source-type scheme as a stand-alone inversion tool we refer to [1, 5, 6, 9, 14, 21, 46, 47].

Our approach is different from those mentioned above. We only want to find a good *approximation* to the scattering potential, and a corresponding *initial level set function* suitable to start the shape reconstruction routine. Moreover, we can make use of our prior information about the permittivity distribution. This will allow us to circumvent most of the problems of source-type schemes which have been mentioned above.

We will now describe this method, which we will call the Source-Type Adjoint Field (STAF) method, in more details.

5.2 Solving the inverse scattering problem

Consider the inverse scattering problem formulated in section 3.1. The decomposition (13), (14) reads

$$\tilde{\epsilon}(x) = \epsilon_b(x) + \tilde{\epsilon}_s(x) \quad (70)$$

with some (known) background distribution ϵ_b and the (unknown) scattering potential $\tilde{\epsilon}_s$ having compact support, $\text{supp}(\tilde{\epsilon}_s) \subset \subset B_r(0)$. The goal is to find $\tilde{\epsilon}_s(x)$ from the data (9).

We already mentioned above that we actually will *not* recover the entire function $\tilde{\epsilon}_s(x)$ from the data \tilde{G}_{jk} in this preprocessing step. All we will find is 1.) A very good first guess for the scattering potential $\epsilon_s^{(0)}$ which will be part of the initializing triple $(\Omega^{(0)}, \epsilon_b + \epsilon_s^{(0)}, \phi^{(0)})$, and 2.) A corresponding level set function $\phi^{(0)}$. We will freely make use of the prior information resulting from the knowledge of $\hat{\epsilon}$ inside the estimated scatterer $\Omega^{(0)}$. However, our numerical results so far indicate that the method proposed here -if suitably adapted- can actually be used to find, in addition to $\Omega^{(0)}$ and $\phi^{(0)}$, also a good first estimate $\hat{\epsilon}^{(0)}$ for the contrast $\hat{\epsilon}$. This will be used in our future work to start a reconstruction method which tries to recover $\tilde{\Omega}$ and $\hat{\epsilon}$ *simultaneously* from the given data.

For a fixed frequency f_k and a source q_j , let \tilde{u}_{jk} be the solution of

$$\Delta \tilde{u}_{jk} + (a_k(\epsilon_b + \tilde{\epsilon}_s)(x) + ib\sigma(x)) \tilde{u}_{jk} = q_j(x), \quad (71)$$

and let u_{jk} be the solution of the 'unperturbed' equation

$$\Delta u_{jk} + (a_k \epsilon_b(x) + ib\sigma(x)) u_{jk} = q_j(x). \quad (72)$$

Define

$$\tilde{v}_{jk} := u_{jk} - \tilde{u}_{jk}. \quad (73)$$

Subtraction of (72) from (71) shows that \tilde{v}_{jk} solves

$$\Delta \tilde{v}_{jk} + (a_k \epsilon_b(x) + ib\sigma(x)) \tilde{v}_{jk} = \tilde{Q}_{jk}^s(x), \quad (74)$$

where the 'scattering source' $\tilde{Q}_{jk}^s(x)$ is defined as

$$\tilde{Q}_{jk}^s(x) = a_k \tilde{\epsilon}_s(x) \tilde{u}_{jk}(x). \quad (75)$$

We introduce a 'source type' forward operator A_{jk} by putting

$$A_{jk} : Y \longrightarrow Z_j \quad , \quad A_{jk} Q_{jk}^s = M_j v_{jk} \quad (76)$$

where M_j is the measurement operator defined in (8), and v_{jk} solves

$$\Delta v_{jk} + (a_k \epsilon_b(x) + ib\sigma(x)) v_{jk} = Q_{jk}^s(x). \quad (77)$$

The operator A_{jk} is linear.

Let us assume now that we apply the 'correct' scattering source $\tilde{Q}_{jk}^s(x)$ defined by (75) as argument of A_{jk} . Then we know from (9), (29), (30) that

$$A_{jk} \tilde{Q}_{jk} = M_j \tilde{v}_{jk} = M_j (u_{jk} - \tilde{u}_{jk}) = M_j u_{jk} - \tilde{G}_{jk} = R_{jk}(0). \quad (78)$$

The vectors $R_{jk}(0)$ are easily computed by solving a forward problem on the background distribution (72). Therefore, all we have to do to get back the scattering source \tilde{Q}_{jk}^s from the data \tilde{G}_{jk} is to solve (78) for \tilde{Q}_{jk}^s . Doing so amounts to solving an ill-posed but *linear* inverse problem.

Once we have recovered $\tilde{Q}_{jk}^s(x)$, we want to get back $\tilde{\epsilon}_s(x)$ out of it by using the constitutive relation (75). This second part of the inversion scheme can be interpreted as solving a *nonlinear* inverse problem since $\tilde{u}_{jk}(x)$ depends on $\tilde{\epsilon}_s(x)$.

Notice that $\tilde{Q}_{jk}^s(x)$ varies with different sources and frequencies, but that $\tilde{\epsilon}_s(x)$ is the same for all sources and all frequencies (if we neglect dispersion). We will make use of this observation when we try to solve the nonlinear part (75). In the following, we describe the method which we will use to recover the scattering source $\tilde{Q}_{jk}^s(x)$ from a given data set \tilde{G}_{jk} for a fixed source q_j and a fixed frequency f_k .

5.3 Looking for a scattering source

Since for a fixed (primary) source position and a fixed frequency we have only few data given to recover \tilde{Q}_{jk}^s , and since we have to take into account that also 'non-radiating' and 'invisible' sources have been generated in the experiment, we assume that there will be many solutions (in absence of noise) of (78). To pick one we are looking for the solution with minimal norm

$$\text{Min } \|Q_{jk}^s\|_Y \quad \text{subject to} \quad A_{jk} Q_{jk}^s = R_{jk}(0). \quad (79)$$

It is given by

$$Q_{jk,MN}^s = A_{jk}^* \left(A_{jk} A_{jk}^* \right)^{-1} R_{jk}(0), \quad (80)$$

where A_{jk}^* denotes the adjoint operator to A_{jk} .

The following theorem, which is proven in the appendix, tells us how to calculate the action of A_{jk}^* on a vector $\zeta \in Z_j$ in an efficient way.

Theorem 5.1 *Let $\zeta = (\zeta_1, \dots, \zeta_{D_j})^T \in Z_j$ and let x_{jd} , $d = 1, \dots, D_j$ be the detector positions corresponding to the source q_j . Then, $A_{jk}^* \zeta$ is given by*

$$A_{jk}^* \zeta = \overline{z_{jk}} \chi_{B_r(0)}, \quad (81)$$

where z_{jk} solves

$$\Delta z_{jk} + (a_k \epsilon_b + i b_k \sigma) z_{jk} = \sum_{d=1}^{D_j} \overline{\zeta_d} \delta(x - x_{jd}). \quad (82)$$

Corollary 5.1 *Let $\varphi_{\nu k}$ solve*

$$\Delta \varphi_{\nu k} + (a_k \epsilon_b + i b_k \sigma) \varphi_{\nu k} = \delta(x - x_{j\nu}). \quad (83)$$

Then, we can write (81) in the alternative form

$$\left(A_{jk}^* \zeta \right) (x) = \overline{\sum_{d=1}^{D_j} \zeta_d \varphi_{dk}(x) \chi_{B_r(0)}(x)} = \sum_{d=1}^{D_j} \zeta_d \overline{\varphi_{dk}(x) \chi_{B_r(0)}(x)}. \quad (84)$$

The next theorem, which is proven in the appendix, gives an explicit expression for the operators $A_{jk} A_{jk}^*$.

Theorem 5.2 *Let us assume that we are given a background permittivity distribution ϵ_b and a finite set of receiver positions x_{jd} , $d = 1, \dots, D_j$. The operators $A_{jk} A_{jk}^*$, $j = 1, \dots, p$, $k = 1, \dots, K$, are then described by $D_j \times D_j$ matrices of the form*

$$A_{jk} A_{jk}^* = \left\{ \int_{B_r(0)} \overline{\varphi_{dk}(x)} \varphi_{lk}(x) \right\}_{\substack{l=1, \dots, D_j \\ d=1, \dots, D_j}}, \quad (85)$$

where $\varphi_{\nu k}$ solves (83) and the index ν can stand for a receiver index d or l . In (85), the receiver index l is the row index, and the receiver index d is the column index of \hat{C}_{jk} .

Remark. Notice that (85) does not depend on the sources q_j , but only on the arrangement of the detectors and on the background permittivity distribution ϵ_b . The operators $A_{jk} A_{jk}^*$ can be precomputed before starting the inversion routine,

and this has to be done only once for each frequency as long as we use the same arrangement of detectors for all sources q_j , $j = 1, \dots, p$.

In the case of noisy data we will invert $A_{jk}A_{jk}^* + \lambda I$ instead of $A_{jk}A_{jk}^*$ in (80) with a suitably chosen regularization parameter $\lambda > 0$. This amounts to applying Tychonov-Phillips regularization.

5.4 Recovery of the scattering potential

After we have found a scattering source Q_{jk}^s which satisfies (79), we want to use the constitutive relation

$$Q_{jk}^s(x) = a_k \tilde{\epsilon}_s(x) \tilde{u}_{jk}(x), \quad (86)$$

which holds for the 'correct' scattering source \tilde{Q}_{jk}^s according to (75), to find an approximation for $\tilde{\epsilon}_s(x)$.

Let \tilde{u}_{jk} be a solution of (71) and u_{jk} a solution of (72). We decompose Q_{jk}^s , \tilde{u}_{jk} , u_{jk} and $\tilde{\epsilon}_s$ into amplitude and phase

$$Q_{jk}^s(x) = |Q_{jk}^s(x)| e^{ir(x)}, \quad \tilde{u}_{jk} = |\tilde{u}_{jk}| e^{i\tilde{s}(x)}, \quad (87)$$

$$u_{jk} = |u_{jk}| e^{is(x)}, \quad \epsilon_s(x) = |\epsilon_s(x)| e^{it(x)}, \quad (88)$$

where we have omitted the subscripts jk in the argument functions r , \tilde{s} , s , and t for simplicity in the notation. Making use of the fact that $\tilde{\epsilon}_s(x) \in \mathbb{R}$ we see that

$$t(x) \in \{0, \pi\} \quad \text{for all } x \in \mathbb{R}^2. \quad (89)$$

With (87),(88) equation (79) decomposes into two equations, one for the amplitude and one for the phase. They are

$$|Q_{jk}^s(x)| = a_k |\tilde{\epsilon}_s(x)| |\tilde{u}_{jk}|, \quad (90)$$

$$r(x) = \tilde{s}(x) + t(x). \quad (91)$$

The observation in our numerical experiments is that, although $s(x)$ and $\tilde{s}(x)$ might be quite different from each other for large perturbations $\tilde{\epsilon}_s(x)$, the amplitudes $|u_{jk}(x)|$ and $|\tilde{u}_{jk}(x)|$ most often do not differ too much from each other in the scattering region. Therefore, in our applications it is a reasonable approximation to assume that

$$|\tilde{u}_{jk}(x)| \approx |u_{jk}(x)| \quad \text{in } B_r(0). \quad (92)$$

With this approximation, (90) yields the following estimate for $|\tilde{\epsilon}_s(x)|$

$$|\tilde{\epsilon}_s^{(jk)}(x)| \approx \frac{|Q_{jk}^s(x)|}{a_k |u_{jk}(x)|} \quad \text{in } B_r(0). \quad (93)$$

We have added the indices j and k on the left hand side of (93) to indicate that we have used only the data \tilde{G}_{jk} corresponding to source q_j and frequency f_k for its determination.

Notice that the step (92), (93) is *nonlinear* since taking the amplitude of a complex number is a nonlinear operation. Therefore, the approach presented here is quite different from the usual Born approximation which approximates \tilde{u}_{jk} by u_{jk} .

For the purposes of the present paper, the determination of $|\tilde{\epsilon}_s(x)|$ is already sufficient in order to get a good first guess for the scattering potential $\epsilon_s^{(0)}(x)$ and for the level set function $\phi^{(0)}(x)$, since we can now make use of our prior information about the correct value of $\hat{\epsilon}$ in (12).

We mention, however, that the recovery of the phase $t(x)$ is also possible from (86). (This will be necessary for example when we try to recover $\tilde{\Omega}$ and $\hat{\epsilon}$ simultaneously from the given set of data \tilde{G}_{jk} .) We can do this by using equation (91). We already mentioned that the assumption $\tilde{s}(x) \approx s(x)$ might be quite wrong for situations with large scattering potentials $\tilde{\epsilon}_s(x)$. However, in our situation we only have to decide whether $t(x)$ is zero or π , which means that we have to determine whether in (91) $r(x) = \tilde{s}(x)$ or $r(x) = \tilde{s}(x) \pm \pi$ is satisfied. Therefore, a reasonable estimate for $t(x)$ is to put

$$t^{(jk)}(x) = \begin{cases} 0 & , \quad |s(x) - r(x)| < \pi/2, \\ \pi & , \quad \text{elsewhere.} \end{cases} \quad (94)$$

Our numerical experiments so far show that a suitable combination of these estimates resulting from many source positions gives a very good reconstruction of the phase $t(x)$ in $B_r(0)$ even in the situation of limited view and noisy data. We will not need this estimate in the present paper.

5.5 Combining the results from single experiments

We can combine now the estimates $|\tilde{\epsilon}_s^{(jk)}(x)|$ from many source positions q_j , $j = 1, \dots, p$, by putting

$$|\tilde{\epsilon}_s^{(k)}(x)| = \frac{1}{p} \sum_{j=1}^p |\tilde{\epsilon}_s^{(jk)}(x)|. \quad (95)$$

If we want to take into account also the information corresponding to many frequencies we can do so by putting

$$|\tilde{\epsilon}_s(x)| \approx \frac{1}{pK} \sum_{k=1}^K \sum_{j=1}^p |\tilde{\epsilon}_s^{(jk)}(x)| \quad (96)$$

where the sum is over all frequencies f_k , $k = 1, \dots, K$, and all source positions q_j , $j = 1, \dots, p$. In (96) we have neglected dispersion.

A similar strategy can be employed to improve the estimates for the phase $t^{(jk)}(x)$.

5.6 The initial level set function

We are now ready to define the initial triple $(\Omega^{(0)}, \epsilon^{(0)}, \phi^{(0)})$.

We assume that we are working in a high contrast situation, such that exactly one of the following conditions is satisfied

$$\hat{\epsilon} - \epsilon_b(x) \gg 0 \quad \text{for all } x \in \tilde{\Omega} \quad (97)$$

$$\hat{\epsilon} - \epsilon_b(x) \ll 0 \quad \text{for all } x \in \tilde{\Omega}. \quad (98)$$

Since we know $\hat{\epsilon}$ and $\epsilon_b(x)$, we know the constant

$$\text{sign}(\tilde{\Omega}) := \begin{cases} 1 & , \quad \text{if (97) holds} \\ -1 & , \quad \text{if (98) holds.} \end{cases} \quad (99)$$

Let us assume that we want to use $|\tilde{\epsilon}_s^{(k)}(x)|$ as defined in (95) for a fixed frequency f_k to specify the level set function $\phi^{(0)}$. Choose a threshold value $0 < \gamma_{\text{LS}} < 1$ (in our numerical examples presented in section 6 we use $\gamma_{\text{LS}} = 0.7$) and define

$$\epsilon_{\text{LS}} := \gamma_{\text{LS}} \max_{x \in B_r(0)} |\tilde{\epsilon}_s^{(k)}(x)|. \quad (100)$$

For the level set zero $L_0^{(0)}$ of $\phi^{(0)}$ we require that

$$L_0^{(0)} = \left\{ x \in B_r(0) : |\tilde{\epsilon}_s^{(k)}(x)| = \epsilon_{\text{LS}} \right\}. \quad (101)$$

This means that we want all points of $B_r(0)$ where the reconstruction $|\tilde{\epsilon}_s^{(k)}(x)|$ has exactly the value ϵ_{LS} to be mapped to zero by the level set function $\phi^{(0)}$

$$\phi^{(0)}(x) = 0 \quad \text{for all } x \in L_0^{(0)}. \quad (102)$$

The level set function is now defined as

$$\phi^{(0)}(x) = C_{\text{LS}}^{(0)} \text{sign}(\tilde{\Omega}) \left(\epsilon_{\text{LS}} - |\tilde{\epsilon}_s^{(k)}(x)| \right), \quad (103)$$

where $C_{\text{LS}}^{(0)}$ is some suitably chosen scaling factor. Notice that (102) and (103) are consistent.

The initial scattering domain $\Omega^{(0)}$ and the permittivity $\epsilon^{(0)}$ are defined as

$$\Omega^{(0)} = \Omega[\phi^{(0)}], \quad \epsilon^{(0)} = \epsilon_b + \Lambda(\phi^{(0)}). \quad (104)$$

Together with $\phi^{(0)}$ they form an admissible triple $(\Omega^{(0)}, \epsilon^{(0)}, \phi^{(0)})$.

5.7 Implementation: The STAF algorithm

In brief algorithmic form, the Source Type Adjoint Field (STAF) scheme can be written in the following way.

Preparation step.

- Select a group of frequencies $G_s = \{f_1, \dots, f_{K_s}\}$ which are used for the STAF reconstruction. Typically, this is just one frequency.
- Calculate $A_{jk}A_{jk}^*$ according to (85) for each frequency $f \in G_s$. The operator $A_{jk}A_{jk}^*$ does not depend on the index j if we use the same detector positions for all sources.
- Calculate

$$B_{jk} = \left(A_{jk}A_{jk}^*\right)^{-1} \quad \text{or} \quad B_{jk} = \left(A_{jk}A_{jk}^* + \lambda I\right)^{-1} \quad (105)$$

for all $f \in G_s$ and store in memory for later use.

Reconstruction step.

FOR $k = 1 : K_s$

FOR $j = 1 : p$

$$R_{jk}(0) = M_j u_{jk} - \tilde{G}_{jk}, \quad u_{jk} \text{ solves (72)}$$

$$\zeta_{jk} = B_{jk} R_{jk}(0), \quad B_{jk} \text{ from (105)}$$

$$Q_{jk}^s = A_{jk}^* \zeta_{jk} = \overline{z_{jk}} \chi_{B_r(0)}, \quad z_{jk} \text{ solves (82)}$$

$$|\tilde{\epsilon}_s^{(jk)}(x)| = \frac{|Q_{jk}^s(x)|}{a_k |u_{jk}(x)|}$$

END

END

$$|\tilde{\epsilon}_s(x)| = \frac{1}{pK_s} \sum_{k=1}^{K_s} \sum_{j=1}^p |\tilde{\epsilon}_s^{(jk)}(x)|, \quad x \in B_r(0)$$

$$\phi^{(0)}(x) = C_{\text{LS}}^{(0)} \text{sign}(\tilde{\Omega})(\epsilon_{\text{LS}} - |\tilde{\epsilon}_s(x)|) \quad \text{as in (103)}$$

$$(\Omega^{(0)}, \epsilon^{(0)}, \phi^{(0)}) = (\Omega[\phi^{(0)}], \epsilon_b + \Lambda(\phi^{(0)}), \phi^{(0)}).$$

6 Numerical Experiments

6.1 Discretization of the computational domain.

In our numerical experiments, we use a Finite-Differences Frequency Domain (FDFD) code written in MATLAB for solving (1)-(3). The code uses appropriately designed

perfectly matched layers (PML) to avoid reflections at the artificial computational boundaries [36, 37].

The system which results after discretization is solved by a simple Gauss elimination scheme, which is reflected in the implementation shown in sections 4.10 and 5.7. The LR -factorization corresponding to the most recent best guess is used there to calculate the fields for all transmitters and all receivers simultaneously. Therefore, the computational cost for solving all necessary forward and adjoint problems is just one LR -factorization for STAF, and one LR -factorization per update for levelART. If a different solver is used (e.g. GMRES or QMR), then we might find more efficient strategies than those presented in sections 4.10 and 5.7. We mention also that an iterative solver has been developed recently in [25] which is optimized to work on several source distributions simultaneously.

The physical domain is partitioned into 100×100 elementary cells (pixels) in the first numerical example, and into 180×110 elementary cells in the second and third example. Each of these grid cells has a physical size of about $0.14 \times 0.14 \text{ m}^2$, such that the total computational domain in the first example covers an area of $14 \times 14 \text{ m}^2$, and in the other two examples of $15 \times 25 \text{ m}^2$. The eight layers which are closest to the boundaries of the computational domain are used as a PML.

We will refer to the first numerical example as the 'full-view' situation, and to the other two numerical examples as the 'limited-view', 'cross-borehole' or 'geophysical' situations. This terminology is motivated by the source and receiver geometries used, which are as follows.

In the full-view example, we have 64 sources and receivers given which surround the domain of interest. Each source position is at the same time a receiver position and vice versa. The distance of two adjacent sources or receivers from each other is four pixels or about 55 cm. The area enclosed by these sources and receivers has a size of $10 \times 10 \text{ m}^2$.

In the two limited-view examples, 74 sources and receivers are positioned equally spaced in two boreholes. The distance of two adjacent sources or receivers from each other is again 4 pixels or 55 cm, and the distance of the two boreholes from each other is about 10 m.

We mention that, in all of our numerical examples, the regions beyond the source and receiver positions are part of the inversion problem, too. This means, the area which has to be recovered from the data is the whole area situated between the PML boundaries. In some of our numerical experiments, artifacts can be observed developping in the outer areas during the early stages of the reconstruction process.

We apply time-harmonic dipole sources of the form (11) with frequencies of $f = 5, 10, 15, 20, 25$, or 30 MHz. In our examples, this corresponds to wavelengths

in the background medium between 2 meters for $f = 30$ MHz and 13 meters for $f = 5$ MHz. The size of an individual grid cell is chosen such that each of these wavelengths is sampled by at least 16 pixels in order to avoid numerical artifacts due to undersampling.

The data in our numerical examples are generated by running the FDFD forward modelling code on the correct permittivity and conductivity distributions. Using the same forward code for creating the data and for doing the reconstruction is usually called 'inverse crime'. Therefore, to make sure that the situations we model in our experiments are as realistic as possible, we have tested the forward modelling code thoroughly, and add Gaussian noise with signal-to-noise ratios between 10 and 5 dB to the real and imaginary parts of the generated data.

6.2 A full-view example

Our first numerical example tests whether the derived algorithm is able to reconstruct a relatively complicated shape in the ideal situation where sources and receivers completely surround the area of interest. The geometry of this example is shown in Figure 1. The positions of the sources and receivers are indicated by dots in the Figure. The background medium in this example consists of a homogeneous conductivity distribution $\sigma_b = 3.0 \times 10^{-4}$ Siemens/m, and a homogeneous permittivity distribution $\epsilon_b = 20$. Inside the object, the permittivity is $\hat{\epsilon} = 15$, having a moderate contrast to the background distribution.

Notice that an interesting feature of this geometry is the 'hole' in the body of the object which is difficult to reconstruct. We will see that, during the evolution of the permittivity in levelART, the boundaries of the reconstructed domain will split and merge in the attempt to recover this geometry correctly.

First, we test the STAF algorithm in Figure 2 by reconstructing the permittivity $\epsilon^{(0)}$ using only the data $G_s = \{30 \text{ MHz}\}$. These data are noisy with a signal-to-noise ratio (SNR) of 10 dB in the real and the imaginary parts. Compare the result with the upper left image of Figure 3 where we used (noise-free) data with frequency $G_s = \{5 \text{ MHz}\}$.

A comparison of reconstructed permittivities for different frequencies between 5 and 30 MHz shows that -in the ideal situation of sources and receivers completely surrounding the area of interest- the STAF algorithm usually yields already a decent approximation to the shape of the inclusion when applied to the data with the highest frequencies, whereas it yields a reconstruction with decreasing resolution when applied to data corresponding to lower frequencies.

Therefore, it seems to be most efficient to apply the STAF algorithm directly to the highest frequency data, such that we do not need at all any low-frequency

information for the reconstruction. We will see in the following two geophysical examples that this is certainly not true in applications where we have only data with limited view available. In these cases, the use of lower frequency data stabilizes the reconstruction process, and is necessary for preparing the final reconstruction step using the higher frequency data.

We also want to demonstrate the performance of the levelART reconstruction scheme when applied to this geometry. We start the algorithm by using as initial permittivity $\epsilon^{(0)}$ the low resolution STAF reconstruction which is shown in the upper left image of Figure 3, and the corresponding initial level set function $\phi^{(0)}$. No noise is added to the data. Figure 3 shows different stages in the reconstruction process. We first apply levelART with a frequency of 10 MHz to this initial guess and run it for 30 sweeps. Then, we run levelART with 20 MHz for 30 more sweeps, and finally for another 30 sweeps with 30 MHz. The final reconstruction $\epsilon^{(N)}$ is shown in the lower right image of Figure 3. The final level set function $\phi^{(N)}$ corresponding to this reconstruction is displayed in Figure 14.

We see from this example that the shape reconstruction algorithm using level sets is able to split and merge boundaries easily in order to build up relatively complicated geometries. In the present situation, splitting and merging of boundaries was necessary for building the 'hole' in the reconstructed domain.

6.3 A cross-borehole situation with multiple objects

In our second numerical example, we consider a situation which is typical for geophysical applications. Comparable situations occur for example when we wish to monitor pollutant plumes at environmental cleanup sites from cross-borehole EM data.

We assume that we have 74 sources and receivers equidistantly distributed over two boreholes. The distance of the boreholes from each other is 10 meters, and the distance of two adjacent sources or receivers is 55 cm. The area between the two boreholes has to be monitored given the gathered data. The geometry is shown in Figure 4.

The background permittivity distribution in this example consists of four tilted layers with values of $\epsilon_b = 21$ in the top layer, and then continuing downwards with 20, 19, and again 21 for the deepest layer. The conductivity distribution σ_b is homogeneous with a value of $\sigma_b = 3.0 \times 10^{-4}$ S/m everywhere.

Embedded in this background are three compact inclusions as shown in Figure 4. The permittivity inside these inclusions is $\hat{\epsilon} = 5$, having a high contrast to the background values. The three inclusions are oriented such that there are two 'channels' of background material between them, one of them in the vertical and

one in the horizontal direction. The difficulty in this example is to separate the three inclusions from each other from the limited-view data. In particular, the reconstruction of the vertical channel is critical since we expect that the resolution in the horizontal direction will suffer from the missing data.

Again, we first apply the STAF reconstruction scheme to the data to get a first guess of the permittivity distribution $\epsilon^{(0)}$. Figure 5 shows the result for $G_s = \{30 \text{ MHz}\}$. Comparing this result with the reconstruction for the same frequency in our first numerical example, we conclude that the performance of STAF for high-frequency data is in the limited-view case not as good as in the case where we can use data with full view. We observe that the vertical resolution of the reconstruction is still good, whereas in the horizontal direction severe artifacts build up which reduce the quality of the high-frequency STAF reconstructions as an initial guess for levelART.

Figure 6 shows the corresponding STAF reconstruction using $G_s = \{5 \text{ MHz}\}$. We do not observe any artifacts in this reconstruction which might be caused by the limited view in the data. Therefore, we see that the decreased resolution of STAF using low-frequency data is in this situation compensated by a much higher robustness with respect to missing data. Keeping this in mind, we will typically start our reconstructions in the limited-view geometry by using the STAF result which correspond to (one or more of) the lowest available frequencies.

Starting out from the permittivity $\epsilon^{(0)}$ as shown in Figure 6, and the corresponding level set function $\phi^{(0)}$, we want to use the levelART algorithm in order to calculate a series of shape deformations which transforms the initial shape into the correct permittivity distribution. Figure 6 shows a reconstruction which uses data where the real part and the imaginary part have been contaminated by additive Gaussian noise with a signal-to-noise ratio (SNR) of 10 dB before starting the reconstruction process. Figure 7 shows the same reconstruction scheme, but with an even lower SNR of now 5 dB in the data.

Different strategies are possible for levelART. Which one works best, depends on the specific situation, for example the number and arrangement of sources and detectors, and on the noise level of the data. The strategy we use here (for both SNR values) is the following: First, we apply 20 steps of levelART with a frequency of 15 MHz to the initial guess. The result is shown in the lower left images of Figures 6 and 7. At this stage, the task of splitting the initial object into three subsets is almost completed.

Then, we apply levelART with a combination of three frequencies, namely 20, 25, and 30 MHz. This means that in a given sweep each of these three frequencies is used exactly once in the prescribed order, before starting again with the lowest frequency

(20 MHz) for the new sweep. This final step completes the reconstruction in just a few (about 10) sweeps. The succeeding sweeps do not improve the reconstruction significantly. Moreover, the norms of the residuals approach a constant value as the Figures 8 to 11 show.

Figures 8 to 11 show the evolution of the norms of the residuals during the reconstruction process for different signal-to-noise ratios in the data. The graphs with the symbol 'o' correspond to noiseless data, the graphs for a SNR of 10 dB are indicated by '*', and those for a SNR of 5 dB by '+'.

Figure 8 shows the norms of the residuals for $f = 15$ MHz during the 20 steps using the data with this frequency. The norms of the residuals decrease in all cases continually during the reconstruction process. Figures 9 to 11 show the evolution of the norms during the final 30 sweeps with the frequencies 20, 25 and 30 MHz. We see that after 10 sweeps the residuals approach some constant value which depends on the noise level of the data. In the lower right image of Figure 6, the reconstruction for a signal-to-noise ratio of 10 dB after completion of these 10 sweeps is shown. The corresponding level set function is shown in Figure 15.

Our experience is that marching over the higher frequencies in the described fashion stabilizes the inversion procedure especially in the limited-view situation considered here. However, so far we do not have any theoretical analysis which supports this observation.

Notice the artifacts which appear in the case of an extremely low SNR of 5 dB in Figure 7. These artifacts remain more or less stable when applying levelART with a constant frequency of 15 MHz, and disappear when marching to the higher frequencies in the succeeding reconstruction step. Notice that we also apply a diffusion ('curve shortening') filter for these higher frequencies, see section 4.10.

We observe again that levelART has no problems in propagating and tracking these multiple artifacts, even when they finally shrink and disappear. Notice also that, similar to the first numerical example, the algorithm splits the original boundary in order to arrive at the three separated inclusions forming the final reconstruction.

6.4 A cross-borehole situation with a single inclusion and variable conductivity

In our third numerical example, we want to test a situation where the conductivity inside the inclusions is different from the given background values. Since we did not take these conductivity changes into account when deriving the reconstruction algorithm, the question arises how much the performance of the reconstruction method will be effected by such changes in the conductivity distribution.

We assume therefore that we know the two values $\hat{\epsilon}$ and $\hat{\sigma}$ of the permittivity and the conductivity inside the inclusions, but both of them are different from the background values. We run the STAF routine as usual, which amounts to treating the conductivity changes simply as an additional form of noise. When applying levelART, we calculate the updates $\delta\phi^{(n)}$ for the level set function $\phi^{(n)}$ in the same way as derived above, but when determining the corresponding updated permittivity distribution $\epsilon^{(n)}$, we update at the same time the conductivity distribution $\sigma^{(n)}$ such that $\sigma(x) = \hat{\sigma}$ where the level set function $\phi^{(n)}$ has negative values. Strictly speaking, we still invert only for the permittivity ϵ , but we make use of the fact that inside the obstacles the conductivity and the permittivity are closely related to each other.

Figure 12 shows the geometry of this example, and Figure 13 shows the results for two different conductivity values $\hat{\sigma} = 1.0 \times 10^{-6}$ S/m and $\hat{\sigma} = 1.0 \times 10^{-2}$ S/m. Notice that these two values differ from each other and from the background value $\sigma_b = 3.0 \times 10^{-4}$ S/m by orders of magnitude! In both cases, Gaussian noise has been added to the real and imaginary parts of the data with a signal-to-noise ratio of 10 dB before starting the reconstruction routine.

As before, we start the reconstruction with the STAF guess corresponding to a frequency of 5 MHz. After only six sweeps of levelART, using the frequencies 15, 20, 25, and 30 MHz one after the other in each sweep, we arrive in both cases at a very good reconstruction of the permittivity distribution and of the conductivity distribution. We conclude that the performance of the reconstruction method (STAF and levelART) is not significantly effected by the changes in the conductivity distribution.

This robustness with respect to changes in the conductivity certainly has its limits. However, the example presented here makes us confident that in practical situations, when the conductivity value $\hat{\sigma}$ inside the obstacles is approximately known and not too large ($< 1.0 \times 10^{-2}$ S/m), the shape reconstruction method will perform stably and reliably and will give us a good reconstruction of the actual permittivity distribution.

7 Summary and future directions

We have presented a stable and efficient two-step shape reconstruction algorithm for EM cross-borehole tomography which uses adjoint fields and level sets. We have shown that this method is able to recover one or more objects with nontrivial shapes given noisy cross-borehole EM data.

The first step of this combined inversion scheme plays the role of an initializing procedure for the second step, and employs a 'source-type' inversion scheme to deal

with the high nonlinearity in the problem due to the presence of strong scatterers.

Although we believe that the preprocessing routine we propose here will work well in most situations, it can be replaced by any other preprocessing tool which shares the main features of the derived algorithm.

The second step of the inversion routine starts directly with the outcome of this initializing procedure, and continues by using a combination of an 'adjoint field technique' and a level set representation of the shapes until the inversion task is completed. We have shown that using a level set representation in this second step enables us to easily describe and keep track of complicated geometries which arise during the inversion process.

We mention that the FDFD routine, which has been employed in both steps to solve the forward and the adjoint Helmholtz problems, can be replaced by any other more efficient Helmholtz solver which has been tested to work reliably in the given situation.

We have shown in our numerical experiments that the proposed reconstruction scheme performs stably with respect to changes in the conductivity distribution, although these conductivity changes have not been taken into account for the derivation of the scheme. It would be desirable, however, to extend the reconstruction scheme to work simultaneously on the permittivity and the conductivity distribution. This seems to be possible, and we will address this problem in our future work.

We also assume that we know the permittivity values inside the obstacles, and that we only have to recover their shapes and their locations. In our future research, we will investigate the situation where both, the shapes and the permittivity values inside the obstacles, have to be recovered from the given data.

Throughout the paper, we have not clearly specified the degree of regularity which we require for the level set functions ϕ representing the domains Ω . A possible choice would be $\phi \in C_0^1(B_r(0))$ (i.e. continuously differentiable on $B_r(0)$ and zero on $\partial B_r(0)$), which would require some additional regularization in our numerical experiments. We also have introduced in (72) an approximated linearized operator $\Lambda'[\phi]$ motivated by our wish to use convenient inner products. Are there any function spaces which are more useful for our purposes? Will a practically useful reconstruction scheme result if we use different inner products instead of introducing $\Lambda'[\phi]$? To answer both questions, a thorough theoretical analysis has to be done to investigate the implications of using different function spaces for the level set representation.

The main ideas of the reconstruction method presented here are not restricted to a 2D geometry. Therefore, we believe that it is possible to extend the method to a more realistic 3D situation. All what is needed for this is an efficient forward

solver for the 3D system of Maxwell's equations. A forward solver which has been tested for such situations has been presented in [7, 18]. Moreover, applications to situations in medical imaging [2, 11], or in the nondestructive testing of materials [45], seem interesting and possible.

9 Appendix

9.1 Proof of theorem 5.1

Green's formula for an infinite domain (without boundary terms since $\sigma > 0$) reads for general v, z

$$\begin{aligned} \int_{\mathbb{R}^2} [\Delta v + \kappa_k v] z \, dx + \int_{\mathbb{R}^2} v(x) \left(\sum_{d=1}^{D_j} \overline{\zeta_d} \delta(x - x_{jd}) \right) dx \\ = \int_{\mathbb{R}^2} v [\Delta z + \kappa_k z] \, dx + \sum_{d=1}^{D_j} \left(\int_{\mathbb{R}^2} v(x) \delta(x - x_{jd}) dx \right) \overline{\zeta_d} \end{aligned} \quad (106)$$

where we have used the notation $\kappa_k = a_k \epsilon_b + i b_k \sigma$. Let now v_{jk} be a solution of (77), and z_{jk} a solution of (82). Then the first term on the left hand side of (106) reads

$$\int_{\mathbb{R}^2} Q_{jk}^s(x) z_{jk}(x) \, dx = \left\langle Q_{jk}^s, \overline{z_{jk}} \chi_{B_r(0)} \right\rangle_Y, \quad (107)$$

whereas the second term on the right hand side is

$$\langle M_j v_{jk}, \zeta \rangle_{Z_j} = \left\langle A_{jk} Q_{jk}^s, \zeta \right\rangle_{Z_j}. \quad (108)$$

The remaining two terms cancel each other because of (82). Therefore, (106) gets the form

$$\left\langle Q_{jk}^s, \overline{z_{jk}} \chi_{B_r(0)} \right\rangle_Y = \left\langle A_{jk} Q_{jk}^s, \zeta \right\rangle_{Z_j}, \quad (109)$$

which proves the theorem.

9.2 Proof of theorem 5.2

Since $A_{jk}A_{jk}^*$ is a linear operator acting on the finite-dimensional data space, it is sufficient to find the action of $A_{jk}A_{jk}^*$ on each of the basis vectors $e_d = (0, \dots, 0, 1, 0, \dots, 0)^T$, $d = 1, \dots, D_j$, where the '1' is at the d -th position. From (83) we see that

$$\left(A_{jk}^* e_d\right)(x) = \overline{\varphi_{dk}(x)} \chi_{B_r(0)}(x). \quad (110)$$

Application of A_{jk} yields for the l -th component ($l = 1, \dots, D_j$)

$$\left(A_{jk}A_{jk}^* e_d\right)_l = v_{jk}(x_{jl}), \quad (111)$$

where v_{jk} is given by

$$v_{jk}(y) = \int_{B_r(0)} G_k(y, x) \overline{\varphi_{dk}(x)} dx \quad (112)$$

and $G_k(y, x)$ is Green's function satisfying

$$\Delta G_k(y, x) + (a_k \epsilon_b + i b_k \sigma) G_k(y, x) = \delta(y - x). \quad (113)$$

Reciprocity yields $G_k(x_{jl}, x) = \varphi_{lk}(x)$. Therefore, we get from (111), (112)

$$\left(A_{jk}A_{jk}^* e_d\right)_l = \int_{B_r(0)} \varphi_{lk}(x) \overline{\varphi_{dk}(x)} dx, \quad (114)$$

which proves the theorem.

Abstract

In this paper we examine the problem of locating an object in an image when size and rotation are unknown. Previous work has shown that with known geometric parameters, an image restoration method can be useful by estimating a delta function at the object location. When the geometric parameters are unknown, this method becomes impractical because the likelihood surface to be minimized across size and rotation has numerous local minima and areas of zero gradient. In this paper, we propose a new approach where a smooth approximation of the template is used to minimize a well-behaved likelihood surface. A coarse-to-fine approximation of the original template using a diffusion-like equation is used to create a library of templates. Using this library, we can successively perform minimizations which are locally well-behaved. As detail is added to the template, the likelihood surface gains local minima, but previous estimates place us within a well-behaved “bowl” around the global minimum, leading to an accurate estimate. Numerical experiments are shown which verify the value of this approach.

EDICS

1 Introduction

A common image processing problem is to determine the location of an object using a template when the size and rotation of the true target are unknowns [1–3]. An algorithm for finding the solution should be robust to noise, accurate across a wide range of object configurations, and computationally efficient. With known geometric parameters (i.e. size and rotation) and additive Gaussian noise, the classic solution for object localization is a whitening filter followed by a matched filter. Other estimators have been proposed, such as the phase only matched filter (POMF) and the symmetric phase only matched filter (SPOMF) which give better location discrimination than the standard matched filter [3]. However these filters do not use additional information regarding the background noise which may be available or estimable. Alternatively, one may formulate the localization problem in the framework of image reconstruction, where the image to be recovered is a delta function at the location of the object and the blurring kernel is the template to be matched [1]. This approach makes available image reconstruction methods such as the linear least squares estimator (LLSE) and maximum likelihood estimator which can incorporate background statistics. The final step is simply to select the point of highest response in the recovered image.

Since they rely upon an accurate template the methods mentioned above are not sufficient when geometric parameters such as size and rotation are unknown. Here, one must compose an estimator which is invariant to these parameters or simultaneously estimate these parameters. With the invariant approach [4–7], a discriminant function is composed in the spatial, frequency or another domain which is invariant to an affine transformation of the template. The discriminant function is usually computed from local or global features of the image, boundaries within the image or regions of the image. The invariant function score can then be used for detection or classification. The second approach and the one followed in this paper is to estimate the parameters. By estimating

the parameters, an accurate template match can be achieved as in the methods mentioned earlier. This approach is also taken with the Fourier Mellin Matched Filter (FMMF) [2]. In the FMMF, the amplitude of the Fourier transform is mapped to a log-polar coordinate system. The translational dependence is eliminated because it appears only in the phase of the Fourier transform. The transformation to the log-polar coordinate system converts the rotation and scaling parameters into translational parameters. Scale and rotation are then solved with a matched filter or phase only matched filter. While computationally fast and a simple method, it is not very robust to noise or clutter. Additionally if the template does not accurately match the object in the image, this method again will often fail. Another approach is to minimize a likelihood surface defined from the difference between the matched template and the image. However, this surface is not amenable to minimization due to numerous local minima and areas of small or zero gradient. Randomized techniques can be used to minimize the surface such as simulated annealing [8, 9] or by using a jump diffusion technique [10, 11]. Here one updates the parameter set with a step increment, the increment becoming smaller as the algorithm runs until it settles into, hopefully, the global minimum.

We propose a deterministic method for searching this surface using a progression of templates. The early templates are smooth approximations of the exact template. This results in a search of a well-behaved approximation of the true likelihood surface and therefore we can get close to the global minimum of the cost surface. A standard optimization routine such as the Newton algorithm can be used to find the best fit solution. Using this estimate as a starting point, we add more detail to our template and search again. As we add detail, the surface becomes more ill-behaved, but the previous estimates have placed us within a “basin of attraction” of the global minimum. This method is similar to the Graduated Non-Convexity (GNC) approach [12–14] in that it allows us to locally search a series of approximations to the likelihood surface and in a small number of

iterations will carry us to an accurate solution. To generate the templates for the search, we use a diffusion like equation which allows fast Fourier based computations of the templates, coupled with the Fourier based image restoration method [1]. This leads to a Fourier domain algorithm which is not computationally burdensome.

We demonstrate the performance of the algorithm using synthetic images, infrared images and optical images. The experimental evidence shows that this approach is able to accurately estimate the size, rotation and location of an object across a wide range of signal to noise ratios and clutter.

In Section 2 we will introduce the problem setup and the solution method via an impulse estimation routine. In Section 3, we present a method for developing the template library. Section 4 shows the Newton algorithm used for parameter estimation. Section 5 discusses the Cramer-Rao bounds of the parameter estimates. In Section 6, we present our numerical experiments. Finally, in Section 7 we present some conclusions and directions for future work.

2 Background

Abu-Naser et. al. [1] formulated the problem of template matching with an image restoration framework, taking a delta function at the template location as the signal to be restored and the target template as the blurring kernel, which leads to the convolution equation,

$$g(\mathbf{r}) = f(\mathbf{r}; \boldsymbol{\theta}^0) * \delta(\mathbf{r} - \bar{\mathbf{r}}^0) + n(\mathbf{r}). \quad (1)$$

where the position vector $\mathbf{r}^T = [r_x \ r_y]$, and $*$ represents two dimensional convolution. Here the object is represented by the template, f , at some location $\bar{\mathbf{r}}^0$. We have described the template using a parameter set, $\boldsymbol{\theta}$ (where $\boldsymbol{\theta}^0$ is the true parameter set), which specifies the geometric parameters

of the template (i.e. the size s and rotation ϕ), as

$$\boldsymbol{\theta}^T = [s \ \phi]. \quad (2)$$

The template is a rotated and resized version of the standard template, $f(\mathbf{r})$, given as

$$f(\mathbf{r}; \boldsymbol{\theta}) = f\left(\frac{1}{s}\mathbf{M}(\phi)\mathbf{r}\right), \text{ where } \mathbf{M}(\phi) = \begin{bmatrix} \cos \phi & -\sin \phi \\ \sin \phi & \cos \phi \end{bmatrix}. \quad (3)$$

As in [1] for estimation purposes we assume that the noise and the δ are zero-mean stochastic functions with spectra given as

$$S_\delta(\mathbf{k}) = \sigma_\delta^2 \text{ and, } S_n(\mathbf{k}) = \sigma_n^2, \quad (4)$$

where $\mathbf{k}^T = [k_x \ k_y]$ are the spatial frequencies used in the two dimensional Fourier Transform

$$\tilde{f}(\mathbf{k}) = \mathcal{F}\{f(\mathbf{r})\} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} f(\mathbf{r}) \exp(-j2\pi\mathbf{k} \cdot \mathbf{r}) \, d\mathbf{r}. \quad (5)$$

With this framework, we now use a maximum likelihood estimate of the parameter set $\hat{\boldsymbol{\theta}}$, while using the delta restoration method [1] for the location estimation $\hat{\mathbf{r}}$. Since the additive noise is assumed Gaussian, the negative log-likelihood for our parameters is

$$l(\boldsymbol{\theta}, \bar{\mathbf{r}}|g) = \frac{1}{\sigma_n^2} \|f(\mathbf{r}; \boldsymbol{\theta}) * \delta(\mathbf{r} - \bar{\mathbf{r}}) - g(\mathbf{r})\|_2^2. \quad (6)$$

The maximum likelihood solution is then achieved by minimizing (6) as

$$\{\hat{\mathbf{r}}, \hat{\boldsymbol{\theta}}\} = \arg \min_{\{\bar{\mathbf{r}}, \boldsymbol{\theta}\}} l(\boldsymbol{\theta}, \bar{\mathbf{r}}|g). \quad (7)$$

With a given set of geometric parameters $\boldsymbol{\theta}$, we can construct an estimate of position following Abu-Naser [1] by first making a Linear Least Squares Estimate (LLSE) of the delta function, [1]

$$\hat{\delta}(\mathbf{r}) = \mathcal{F}^{-1} \left\{ \frac{\tilde{f}_0^*(\mathbf{k}; \boldsymbol{\theta})}{|\tilde{f}_0(\mathbf{k}; \boldsymbol{\theta})|^2 + \left(\frac{\sigma_n}{\sigma_\delta}\right)^2} \tilde{g}(\mathbf{k}) \right\}, \quad (8)$$

and selecting the point of maximum response as our position estimate, as

$$\hat{\mathbf{r}}(\boldsymbol{\theta}) = \arg \max_{\mathbf{r}} \hat{\delta}(\mathbf{r}). \quad (9)$$

Substituting (9) into (7), we have the maximum likelihood estimator, $\hat{\boldsymbol{\theta}}$ as

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}} \frac{1}{\sigma_n^2} \|f(\mathbf{r}, \boldsymbol{\theta}) * \delta(\mathbf{r} - \hat{\mathbf{r}}(\boldsymbol{\theta})) - g(\mathbf{r})\|_2^2 \equiv \arg \min_{\boldsymbol{\theta}} J(\boldsymbol{\theta}; f). \quad (10)$$

The minimization of $J(\boldsymbol{\theta}; f)$ could be accomplished by calculating $J(\boldsymbol{\theta}; f)$ on a dense grid in the $\phi - s$ space to find the minimum point. However, the calculations required to perform this are generally prohibitive. The computation of the surface shown in Figure 1 needed 67 billion flops. Instead, we seek to use standard optimization tools to find the minimum, , the gradient descent algorithm we propose used only 260 million flops to find the minimum of the surface in Figure 1. The problem which we encounter when we attempt to do this is that the likelihood surface is not amenable to a gradient descent methods because of local minima and other areas of zero gradient. We find that these problem areas are a direct result of the shape of the template, f ; specifically,

non-convexities in the template lead to non-convexities in the likelihood surface. By non-convexities we mean a template which when viewed as a surface (height as a function of position in the image plane) has multiple extreme points, instead of a surface which has a single minimum or maximum. This can be seen in Figure 1 where we have a simple non-convex target template and the $J(\theta; f)$ surface directly below it. The example given here is for estimating the same two peaked object with size $s = 1$ and rotation $\phi = 0$ with noiseless data. We can see that the minimum of this surface is a sharp point at the correct parameters, but the irregularity of the surface makes descent-type minimizations impractical. Conversely, if we use a smooth rotationally invariant template, shown on the right, to perform the match we obtain the second surface which is far better behaved. The minimum of this surface while close to 1.0 is much broader in the direction of s , meaning that the estimate of s is not as accurate as the estimate which can be produced by the exact template. As for rotation, the second template gives no information whatsoever as it is rotationally invariant. Thus the primary objective of this work is to capture the accuracy of the exact template estimation with the more easily minimizable surface of the approximate template.

We formulate a method which uses smooth approximate templates which allow us to minimize on a well-behaved surface. Since the results of the minimizations which we obtain from the approximations are not as accurate as those which could be obtained from the exact template, we will add detail back to our templates and minimize again with the previous estimate starting our current estimate within a well-behaved region around the global minimum.

3 Template Progression

In this section we will detail a method of generating target templates which are approximations of the true template but which are sufficiently smooth so that the likelihood surface is locally

well-behaved. This will allow us to make successive estimates beginning at smooth approximation which will generally locate us near the global optimum and refine that estimate with more detailed approximations of the template until a sufficiently accurate estimate of the parameters is reached.

We will generate a spectrum of templates, indexed by t as f_t , ranging from a smooth template f_0 to the exact template $f = \lim_{t \rightarrow \infty} f_t$. We desire that the most smooth template be convex to induce the behavior in the likelihood surface which we discussed in the previous section. A relatively simple choice of this is a Gaussian blob matched (in the two-norm sense) in size and amplitude to the original template given as

$$f_0(\mathbf{r}) = A \exp\left(-\frac{\|\mathbf{r}\|_2^2}{2w^2}\right). \quad (11)$$

While successive estimation will hopefully locate us inside a “well of attraction” of the global minimum where we will avoid local minima, discontinuities in any template can yield discontinuities on our surface. We therefore choose a method for generating templates which in the continuous domain produces continuous templates. A diffusion like process performs this adequately. We specify the Fourier transform of a template f_t as

$$\tilde{f}_t(\mathbf{k}) = \left(\tilde{f}_E(\mathbf{k}) - \tilde{f}_0(\mathbf{k})\right) \exp\left(\frac{-\|\mathbf{k}\|^2}{t}\right) + \tilde{f}_0(\mathbf{k}), \quad (12)$$

where \tilde{f}_E and \tilde{f}_0 are the Fourier transforms of the exact and most smooth templates, respectively.

A progression for the two peak template is shown in Figure 2. We see that at small values of t , the template is a smooth approximation of the true template, as t increases, the true template emerges. Associated with this are the likelihood surfaces related to each template. Here we see that at small values of t , the surface is very smooth has no rotational localization and a very broad scale localization. As t increases, the ill-behavior returns, but previous estimates place us within

the area of the global minimum, and our estimate becomes more accurate. The final solution for the parameters will of course be a local minimum, but may not necessarily be the global minimum. As will be shown later, the rate at which the templates evolve influences the final outcome of the optimization. Slower t -schedules as expected lead to more accurate estimates of the global minimum.

We can now describe a complete algorithm using the template progression as

1. Begin at $t = 0$.
2. Construct f_t with (12).
3. Minimize the likelihood surface constructed via the equations

$$\hat{\mathbf{r}}_t(\boldsymbol{\theta}) = \arg \max_{\mathbf{r}} \mathcal{F}^{-1} \left\{ \frac{\tilde{f}_t^*(\mathbf{k}; \boldsymbol{\theta})}{|\tilde{f}_t(\mathbf{k}; \boldsymbol{\theta})|^2 + \left(\frac{\sigma_n}{\sigma_\delta}\right)^2} \tilde{g}(\mathbf{k}) \right\}. \quad (13)$$

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}} \frac{1}{\sigma_n^2} \|f_t(\mathbf{r}; \boldsymbol{\theta}) * \delta(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta})) - g(\mathbf{r})\|_2^2. \quad (14)$$

The minimization in 14 is performed via a Newton algorithm given in section 4.

4. Increase t and proceed to step 2. The t -schedule should be chosen to take small steps at low values of t where the algorithm is more sensitive to changes in the likelihood surface. This agrees with the observations in [13] for the method of graduated non-convexity and also demonstrated in the analysis of the bounds on estimation accuracy in Section 5. In our implementation, a small value is chosen for the initial value of t and it is doubled for each subsequent t . If a longer schedule is desired, a smaller multiplier is used.

4 Newton Algorithm

The Newton algorithm [15] is used for the minimizations in our paper. The Newton algorithm implemented here seeks to minimize the squared error in the estimated image against the data according to

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}} J(\boldsymbol{\theta}; f_t) = \arg \min_{\boldsymbol{\theta}} \int e_t^2(\mathbf{r}; \boldsymbol{\theta}) d\mathbf{r} \quad (15)$$

where e_t is the error image given as

$$e_t(\mathbf{r}; \boldsymbol{\theta}) = f_t(\mathbf{r}; \boldsymbol{\theta}) * \delta(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta})) - g(\mathbf{r}). \quad (16)$$

The Newton iterative procedure produces updates of the parameter vector as [15]

$$\boldsymbol{\theta}^{(k+1)} = \boldsymbol{\theta}^{(k)} + \mathbf{p}^{(k)}, \quad (17)$$

$$\text{with } (\mathbf{U}_t(\boldsymbol{\theta}^{(k)}) + \mathbf{S}_t(\boldsymbol{\theta}^{(k)}))\mathbf{p}^{(k)} = - \int \mathbf{J}_t(\mathbf{r}; \boldsymbol{\theta}^{(k)}) e_t(\mathbf{r}; \boldsymbol{\theta}^{(k)}) d\mathbf{r}, \quad (18)$$

where $\mathbf{p}^{(k)}$ is the update vector for the parameter set, \mathbf{J}_t is the Jacobian vector of the error function, and \mathbf{U}_t and \mathbf{S}_t are functions of the Jacobian and Hessian that are described below.

The Jacobian vector is the vector of first derivative functions of the of the error as

$$\begin{aligned} \mathbf{J}_t(\mathbf{r}; \boldsymbol{\theta}) &= \nabla_{\boldsymbol{\theta}} e_t(\mathbf{r}; \boldsymbol{\theta}) = \left[\frac{\partial e_t(\mathbf{r}; \boldsymbol{\theta})}{\partial s} \quad \frac{\partial e_t(\mathbf{r}; \boldsymbol{\theta})}{\partial \phi} \right]^T \\ &= \nabla_{\boldsymbol{\theta}} f_t(\mathbf{r}; \boldsymbol{\theta}) * \delta(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta})) + f_t(\mathbf{r}; \boldsymbol{\theta}) * \delta(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta})) * \nabla_{\boldsymbol{\theta}} \delta(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta})) \end{aligned} \quad (19)$$

$$= \nabla_{\boldsymbol{\theta}} f_t(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta}); \boldsymbol{\theta}) - \nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta}) \nabla_{\mathbf{r}} f_t(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta}); \boldsymbol{\theta}). \quad (20)$$

The first term of (20) is directly computable from the template function, however the second term is

troublesome. The gradient $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$ is not guaranteed to exist everywhere, and even if it does exist, it cannot be calculated in closed form since $\hat{\mathbf{r}}_t(\boldsymbol{\theta})$ involves a maximization. Numerical computation of $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$ is also complicated by the large granularity of image pixels with respect to the usual size of $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$. By this, we mean that if we attempt to approximate an element of $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$ (for example $\frac{\partial \hat{r}_x(\boldsymbol{\theta})}{\partial s}$) by the relation

$$\frac{\partial \hat{r}_x(s, \phi)}{\partial s} \approx \frac{\hat{r}_x(s + \Delta s, \phi) - \hat{r}_x(s, \phi)}{\Delta s}, \quad (21)$$

we find that the numerator is either zero (if the two estimates of position are usually the same pixel), or arbitrarily large (if they are different pixels) because Δs is made small. Therefore we used an alternative method to obtain a more accurate approximation of the elements of $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$. First we increase s until $\hat{r}_x(s, \phi)$ moved at least by a pixel and denoted this point by s_1 . Similarly, we then find another point by decreasing s and this point is denoted by s_2 . The derivative is then approximated by

$$\frac{\partial \hat{r}_x(s, \phi)}{\partial s} \approx \frac{\hat{r}_x(s_2, \phi) - \hat{r}_x(s_1, \phi)}{s_2 - s_1}. \quad (22)$$

A similar approach was used to compute the remaining three elements of $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$, that is $\frac{\partial \hat{r}_y(\boldsymbol{\theta})}{\partial s}$, $\frac{\partial \hat{r}_x(\boldsymbol{\theta})}{\partial \phi}$, and $\frac{\partial \hat{r}_y(\boldsymbol{\theta})}{\partial \phi}$.

The disadvantage of this method is that it is computationally intensive since we must calculate $\hat{\mathbf{r}}_t(\boldsymbol{\theta})$ at many points. Using this method, we find that the elements of the matrix $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$ are typically two to three orders of magnitude smaller than $\nabla_{\boldsymbol{\theta}} f_t(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta}); \boldsymbol{\theta})$ in (20). This is demonstrated by the figures in Table 1, which shows a comparison between the average magnitude of $\nabla_{\boldsymbol{\theta}} f_t(\mathbf{r}; \boldsymbol{\theta})$ and the elements of $\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta})$ for 20 runs (1095 iterations) of the algorithm for the two-peak example shown earlier. It is reasonable therefore to simplify the calculation by eliminating this term, and

using the approximation for the Jacobian given by

$$\mathbf{J}_t(\mathbf{r}; \boldsymbol{\theta}) \approx \nabla_{\boldsymbol{\theta}} f_t(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta}); \boldsymbol{\theta}). \quad (23)$$

The Hessian of the error, or the matrix of second derivatives, is

$$\begin{aligned} \mathbf{H}_t(\mathbf{r}; \boldsymbol{\theta}) = \nabla_{\boldsymbol{\theta}}^2 e_t(\mathbf{r}; \boldsymbol{\theta}) = & [\nabla_{\boldsymbol{\theta}}^2 f_t(\mathbf{r}; \boldsymbol{\theta}) - \nabla_{\boldsymbol{\theta}}^2 \hat{\mathbf{r}}_t(\boldsymbol{\theta}) \nabla_{\mathbf{r}} f_t(\mathbf{r}; \boldsymbol{\theta}) \\ & - 2 \nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta}) \nabla_{\boldsymbol{\theta}} \nabla_{\mathbf{r}} f_t(\mathbf{r}; \boldsymbol{\theta}) + (\nabla_{\boldsymbol{\theta}} \hat{\mathbf{r}}_t(\boldsymbol{\theta}))^2 \nabla_{\mathbf{r}}^2 f_t(\mathbf{r}; \boldsymbol{\theta})] * \delta(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta})) \end{aligned} \quad (24)$$

Similarly to the Jacobian, the terms of the Hessian which contain the gradients of $\hat{\mathbf{r}}_t(\boldsymbol{\theta})$ are usually not significant and can cause computational problems, so we disregard those terms. The approximate Hessian which we used is given by

$$\mathbf{H}_t(\mathbf{r}; \boldsymbol{\theta}) \approx \nabla_{\boldsymbol{\theta}}^2 f_t(\mathbf{r} - \hat{\mathbf{r}}_t(\boldsymbol{\theta}); \boldsymbol{\theta}). \quad (25)$$

The two matrices on the left hand side of (18) are computed from the Jacobian and Hessian. The first is the inner product of the Jacobian with itself, and the second is given as the integral of the Hessian components with the error. Therefore,

$$\mathbf{U}_t(\boldsymbol{\theta}) = \int \mathbf{J}_t(\mathbf{r}; \boldsymbol{\theta}) \mathbf{J}_t^T(\mathbf{r}; \boldsymbol{\theta}) d\mathbf{r}. \quad (26)$$

Specifying the elements of $\mathbf{S}_t(\boldsymbol{\theta})$, by $s_{i,j}(\boldsymbol{\theta})$ and the elements of $\mathbf{H}_t(\mathbf{r}; \boldsymbol{\theta})$ by $h_{i,j}(\mathbf{r}; \boldsymbol{\theta})$ we have

$$s_{i,j}(\boldsymbol{\theta}) = \int h_{i,j}(\mathbf{r}; \boldsymbol{\theta}) e_t(\mathbf{r}; \boldsymbol{\theta}) d\mathbf{r}. \quad (27)$$

The Newton algorithm is then an iteration of (18) and (17) until the likelihood as evaluated by

(10) ceases to change significantly. That is while

$$J(\boldsymbol{\theta}^{(k)}; f_t) - J(\boldsymbol{\theta}^{(k-1)}; f_t) > \tau \quad (28)$$

for some small value of τ .

5 Performance and Bounds

The variance of the parameter estimates is constrained by the Cramer-Rao (CR) bounds. We find that the CR lower bounds upon the estimates are a function of the noise power and the mismatch between the approximate template and the true target template. As a function of the approximate template, the bounds show the accuracy of the estimates at various values of t . Furthermore since they are proportional to the curvature of the local basin of attraction of the likelihood surface, they can also describe the manner in which the surface is evolving.

We will arrive at the bounds as the diagonal elements of the inverse of the Fisher information matrix [16, 17]. Since we can express the likelihood as a function of the error as

$$l_t(\boldsymbol{\theta}, \bar{\mathbf{r}}; g) = \frac{1}{\sigma_n^2} \int e_t^2(\mathbf{r}; \boldsymbol{\theta}, \bar{\mathbf{r}}) d\mathbf{r}, \quad (29)$$

we can express the derivatives with respect to the template parameters as

$$\frac{\partial l_t(\boldsymbol{\theta}, \bar{\mathbf{r}}; g)}{\partial \theta_i} = \frac{2}{\sigma_n^2} \int e_t(\mathbf{r}; \boldsymbol{\theta}, \bar{\mathbf{r}}) \frac{\partial e_t(\mathbf{r}; \boldsymbol{\theta}, \bar{\mathbf{r}})}{\partial \theta_i} d\mathbf{r}, \quad (30)$$

and with respect to location as

$$\frac{\partial l_t(\boldsymbol{\theta}, \bar{\mathbf{r}}; g)}{\partial r_x} = \frac{2}{\sigma_n^2} \int e_t(\mathbf{r}; \boldsymbol{\theta}, \bar{\mathbf{r}}) \frac{\partial e_t(\mathbf{r}; \boldsymbol{\theta}, \bar{\mathbf{r}})}{\partial r_x} d\mathbf{r}, \quad \text{and} \quad \frac{\partial l_t(\boldsymbol{\theta}, \bar{\mathbf{r}}; g)}{\partial r_y} = \frac{2}{\sigma_n^2} \int e_t(\mathbf{r}; \boldsymbol{\theta}, \bar{\mathbf{r}}) \frac{\partial e_t(\mathbf{r}; \boldsymbol{\theta}, \bar{\mathbf{r}})}{\partial r_y} d\mathbf{r}, \quad (31)$$

Expanding the error term, and taking the expectations we arrive at the result

$$\begin{aligned} E \frac{\partial l_t(\boldsymbol{\theta}, \bar{\mathbf{r}}; g)}{\partial \theta_i} \frac{\partial l_t(\boldsymbol{\theta}, \bar{\mathbf{r}}; g)}{\partial \theta_j} &= \frac{4}{\sigma_n^4} \int \frac{\partial f_t(\mathbf{r} - \bar{\mathbf{r}})}{\partial \theta_i} (f_t(\mathbf{r} - \bar{\mathbf{r}}) - f_0(\mathbf{r})) d\mathbf{r} \int \frac{\partial f_t(\mathbf{r} - \bar{\mathbf{r}})}{\partial \theta_j} (f_t(\mathbf{r} - \bar{\mathbf{r}}) - f_0(\mathbf{r})) d\mathbf{r} \\ &\quad + \frac{4}{\sigma_n^2} \int \frac{\partial f_t(\mathbf{r} - \bar{\mathbf{r}})}{\partial \theta_i} \frac{\partial f_t(\mathbf{r} - \bar{\mathbf{r}})}{\partial \theta_j} d\mathbf{r}, \end{aligned} \quad (32)$$

where we take $\bar{\mathbf{r}}^0 = \mathbf{0}$ without loss of generality. The terms with respect to location are similar.

We have a term in the information generated by the model mismatch and another generated by the noise term. We can construct the Fisher information matrix as

$$\mathbf{I} = \begin{bmatrix} E \left(\frac{\partial l}{\partial s} \right)^2 & E \frac{\partial l}{\partial s} \frac{\partial l}{\partial \phi} & E \frac{\partial l}{\partial s} \frac{\partial l}{\partial r_x} & E \frac{\partial l}{\partial s} \frac{\partial l}{\partial r_y} \\ E \frac{\partial l}{\partial s} \frac{\partial l}{\partial \phi} & E \left(\frac{\partial l}{\partial \phi} \right)^2 & E \frac{\partial l}{\partial \phi} \frac{\partial l}{\partial r_x} & E \frac{\partial l}{\partial \phi} \frac{\partial l}{\partial r_y} \\ E \frac{\partial l}{\partial s} \frac{\partial l}{\partial r_x} & E \frac{\partial l}{\partial \phi} \frac{\partial l}{\partial r_x} & E \left(\frac{\partial l}{\partial r_x} \right)^2 & E \frac{\partial l}{\partial r_x} \frac{\partial l}{\partial r_y} \\ E \frac{\partial l}{\partial s} \frac{\partial l}{\partial r_y} & E \frac{\partial l}{\partial \phi} \frac{\partial l}{\partial r_y} & E \frac{\partial l}{\partial r_x} \frac{\partial l}{\partial r_y} & E \left(\frac{\partial l}{\partial r_y} \right)^2 \end{bmatrix}. \quad (33)$$

Then from the elements of the inverse of the Fisher information matrix we have the lower bounds upon the variance of the parameter estimations.

In Figure 3 we see the standard deviation bounds for the estimator versus the progression index t for the two-peak template examined in Section 3. It is seen that the size estimate is least accurate at $t = 0$, and asymptotically approaches the CRB for the exact template as t approaches infinity. The rotational estimate begins unbounded since f_0 has no rotational component. Thus at low

values of t , we can only make a rough estimate of the size and no estimate of rotation. We can see that as the value of t increases, the bounds become lower also, indicating a more accurate estimate may be achievable. The bounds for the location estimate perform similarly to that of size.

In Figure 4 we see the standard deviation bounds versus noise. These behave as expected with exact estimation possible in the no noise case and estimation performance degrading as noise increases.

These bounds also influence the t -schedule, or the rate at which the template evolves. At $t = 0$, the template is smoothest and the estimates are the least accurate; however, this is also when the surface is the most well behaved and has the broadest well around the global minimum. The template must evolve in such a way that the estimate remains within the well. Using the CRB as a gauge of the curvature, we see that initially small changes in t are necessary so as not to too drastically change the surface. However as t increases larger steps can be taken since the surface evolves slower with respect to t . This type of schedule is similar to that used in the Graduated Non-Convexity approach in [12–14].

6 Numerical Experiments

In this section we present numerical experiments from the proposed algorithm and performance comparisons with the Fourier Mellin Matched Filter estimate [2]. We first present a synthetic target estimation example using a Monte Carlo simulation analysis. Then we show results of the proposed algorithm when applied to infrared (IR) and optical images.

Figure 5 (a) shows the two-peak target shown earlier buried in noise with 0 dB SNR. Figure 5 (b) and (c) show the estimates of s and ϕ at each iteration of the Newton algorithm. Here we used a t -schedule with four values, $\{10, 5, 2.5, 0\}$. We see here that the algorithm converged to close to

the true parameters in 25 iterations. The true parameters were a size of 1.0 and a rotation angle of 0.25 the estimations converged to values of 0.9914 for size and 0.2354 for rotation.

In Figure 6, we show scatter plots of estimates from 400 simulations of the two-peak example at varying signal to noise ratios. The true parameters are a size of 0.5 and a rotation of 0.25. The ellipses are used to show estimates which are “accurate”, that is are close to the true parameters. The center of the ellipse is at the true parameters and the ellipses are drawn at 3 times the CRB computed from the equations in the previous section. The interiors of these ellipses can be viewed as regions of sufficient confidence in which “accurate” estimates of the parameters fall. We observe that in (a), (b) and (c), the number of estimates which are outside the ellipse, and are therefore considered misses, decreases. The number of misses increases for the highest SNR because of a bias in the size estimates which when combined with the tightness of the CRB causes us to register more misses at high SNR levels than may be warranted by the fact that these estimates are close to the true parameters.

Table 2 summarizes the Monte Carlo runs of the example just presented. Each line shows the result of 400 simulations of the algorithm for a specific level of noise and t -schedule. The error in the estimates is composed of two components, one caused by the variance of the local minimum around the true parameters, and the second caused by the the algorithm becoming trapped in a local minimum which is far from the true parameters. The first type of error is bounded below by the CR bounds, and in practice is usually so small as to effect the target location estimation by less than one pixel. The second type of error constitutes a catastrophic miss by the algorithm. This error is demonstrated in Figure 7 with a pair of Monte Carlo runs at two different t -schedules. From the first scatter plot, we see that the majority of estimates are grouped around the true parameters, but 35 of the estimates missed dramatically. These are instances where the algorithm became caught in a local minimum which was not the global minimum, and thus resulted in an

enormous error. The second scatter plot shows the same Monte Carlo runs with a t -schedule which has twice as many stops and thus has twice the computational burden. Here, the number of misses was reduced from 35 to 18. By progressing through the t -schedule at a slower rate, we can reduce the chances of become trapped in a local minimum at the expense of more computations.

In Figure 8 the performance for these Monte Carlo runs is compared with that of the Fourier Mellin Matched Filter [2]. The plot shows the standard deviation of the error in the location estimate versus SNR. We see that at high SNR, both methods perform well, but as the SNR decreases then error in the FMMF increases at a faster rate.

Figure 9 shows an example of estimating the size, rotation and location of a vehicle in an IR image. Shown first is the target template which we are using followed by the data image. Below this is are the estimation values for size and rotation for each iteration. The iterations are divided into several sections by vertical dotted lines denoting the respective value of t for each stage of the algorithm. We can see that the algorithm converges in 60 iterations to values which upon matching the template to the data appear to be appropriate. Also shown is the position estimate of the target which also appears to be correct.

Figure 10 shows an example with a real optical image. The first image shows a cup in a simple background which is close to white noise. The second image shows the estimated position of the template with proper size and rotation. We see here that the algorithm settled into this estimate after 42 iterations and that it is an accurate estimate. In Figure 11, we show the output of the Fourier-Mellin matched filter which fails to isolate the true size and rotation for this image.

7 Conclusions and Future Work

In this work we have examined the problem of finding a target in a noisy image. Following in the work of Abu-Naser [1], we represent the problem as an image restoration problem where the object to be reconstructed is a delta function encoding the target location and the blur is a target template. Previous work showed that the restoration can be performed using a LLSE and choosing the location of maximum response [1]. However, this did not consider the problem of unknown geometric parameters, i.e. the size and rotation of the target within the image. To estimate size and rotation of the object, we choose to follow the previous approach for location estimation and minimize the negative of the likelihood function across size and rotation to find the true parameters.

This approach was not amenable to minimization, however, due to local minima and regions of zero derivative on the likelihood surface. To overcome these difficulties, we present a new method of generating a library of target templates which range from smooth convex approximations to the exact target. Using this library of templates, it is possible to sequentially estimate the parameter set using standard optimization tools.

Furthermore, since this method relies upon a functional description of the target template, we believe it to be extensible to more complicated target detection problems. Three dimensional perspective mappings of targets could be functionally described, allowing us to locate a target under a three dimensional rotation. Also, since all targets degenerate to the same template at the extremely smooth scale and the algorithm returns a likelihood score as it converges towards the true parameters, we could perform target classification by allowing our library to branch towards several targets or target classes and pruning those which score poorly. Overall, we believe this algorithm could be extended for multiple target, multiple template recognition with reasonable computational costs.

Statistical Method to Detect Subsurface Objects Using Array Ground Penetrating Radar Data

Xiaoyin Xu, Eric L. Miller, Carey M. Rappaport and Gary D. Sower

Abstract

We introduce a combination of high-dimensional analysis of variance (HANOVA) and sequential probability ratio test (SPRT) to detect buried objects from an array ground penetrating radar (GPR) surveying a region of interest in a progressive manner. Using HANOVA, we exploit the transient characteristic of GPR signals in the time domain to extract information about buried objects at fixed positions of the array. Based on the output of the HANOVA, the SPRT is employed to make detection decisions recursively as the array moves downtrack. The method is on-line implementable and of low computational complexity. Our approach is validated using field-data from a landmine detection application.

Index Terms

Analysis of variance (ANOVA), GPR mine detection, array signal processing, sequential detection, transient signal analysis.

I. INTRODUCTION

Ground penetrating radar (GPR) is widely used in detecting subsurface objects such as buried landmines, unexploded ordnance, and utility lines [1]. Compared with other subsurface sensing technologies, GPR has a few advantages. First, it is sensitive to changes in all three electromagnetic characteristics of a media, electric permittivity, electric conductivity, and magnetic permeability. Thus GPR is capable of detecting both metallic and non-metallic

objects. Second, unlike sensors that can only survey an area directly beneath them, GPR can survey an area in front of it [2, 3]. Therefore a GPR system can be used to detect dangerous objects before the system moves over and past them. This can be important for operations such as buried landmine detection and unexploded ordnance remediation.

A typical GPR transmitter/receiver configuration is shown in Fig. 1(a). The system consists of one transmitter and one receiver. The transmitter emits a short pulse of electromagnetic energy and the receiver collects the echo for a certain time period. The exact type of the transmitter and receiver, shape of the electromagnetic pulse, and system setup depend on the specific application of the GPR [1, 4–6]. To improve performance and efficiency, a GPR array is usually employed to sweep a large area in a relatively short time. Fig. 1(b) shows a typical GPR array moving in the x -direction. At every stop of the array, the GPR array operates in the following sequence: 1) the first transmitter radiates a pulse into the ground and then turns off, 2) the first receiver turns on to collect reflected signal, 3) the first receiver turns off after a short time, usually 10 to 20 ns. The above process repeats from every pair of transmitters and receivers and then the GPR array moves to next position. Based on the echoes, the processing objective is to determine if an object is present in the GPR's field of view.

The inherent near-field nature of the GPR detection problem coupled with the fact that the objects of interest are embedded in an inhomogeneous halfspace with a typically rough interface present some significant challenges in the area of GPR signal processing. Indeed assuming one has detailed knowledge of the air-earth interface as well as the electrical properties of the subsurface, just modeling the received signal using, for example, a three dimensional finite difference time domain code, is a daunting task [4, 7]. The use of such a forward model in any form of on-line processing routine where one might need to account

Fig. 1. Setup, a) a single GPR system, b) a GPR array (plane view).

for e.g. unknown ground structure is clearly infeasible at the current time.

Thus, here we consider detection methods which are less computationally demanding with an eye toward approaches that could be used in real-world scenarios. Our interests are in techniques possessing three important characteristics. First, to reflect the manner in which GPR data are acquired and the nature of the GPR mission, the algorithms should be causal in that they need only the data at the current and previous sensor position to determine whether an object is present in the field of view of the sensor. Second, they should be of low complexity. Preferably the number of calculations would grow linearly with the size of the data set. Finally, the processing schemes should be robust to uncertainties in the GPR environment and hence the particular detailed structure of the received signals.

Current signal processing methods with some or all of these characteristics fall into one of three categories. First, pattern matching methods [8] employ techniques such as fuzzy set theory and neural networks. Such methods can be fast but also require extensive training to function well. Second, image-then-detect techniques [9] employ a beamforming or backpropagation approach to build an image of the subsurface which is then post-processed to detect objects. These approaches generally require the data from the full GPR scan to

form an image and are thus not well suited to on-line computations in which information is processed sequentially as the array proceeds down-track. Finally, there has been much work done in statistical signal processing, where one can employ statistical tools to detect objects and examine quantities such as probability of detection and probability of false-alarm [10].

Here we consider a statistical, transient detection approach. By “transient” we mean that the signals of interest are manifest in the GPR data for a small number of sensor positions and for relatively few samples in any received waveform. For example, in Fig. 2 we plot raw observations obtained by one T/R pair from an EG&G GPR system [11], over an M20 metal mine. Each column of this image is a time-series of observations for a given stop of the array. It is seen that the received GPR signal is transient in two ways. First, for each time-series (i.e. for each column of the image) containing an object signal, the signal appears only in a brief window, roughly from samples 300 to 700. The reason is that the object signal always comes after the signal arising from the bounce off of the air-ground interface and attenuates quickly in lossy media. Second, the object signal shows up only at a few down-track positions of the GPR array, specifically locations 15 through 25. In both cases, the appearance of object signal changes the mean value of the data. Our method for object detection then is based on detecting change in this mean first in the cross-track direction and then in the down-track direction.

More specifically our approach consists of two parts. First, at each down-track position of the array, we process the data among all T/R pairs to generate one test statistic. We use high-dimensional analysis of variance (HANOVA) to test whether the data consists of reflected signal from a buried object. The HANOVA is a generalized version of standard analysis of variance (ANOVA), which is a method for testing hypothesis about means of random vectors [12, 13]. Second, a sequential probability ratio test (SPRT) is applied to

Fig. 2. Observation from one T/R pair, for a metal mine M20 buried at about position 20. Unit in down-track position is about 7.6 cm. Unit in time axes is 0.02 ns.

process the statistic of the HANOVA as the array moves down-track. The SPRT is a recursive statistical hypothesis testing technique that provides early indication of the onset of changes in a time series. The output of the SPRT is compared with a threshold. If it exceeds the threshold, a detection is declared, otherwise, the GPR array moves one more step down-track and new data are collected and processed in the above manner [14].

As explained in greater detail below, our approach does in fact satisfy the three requirements we discussed previously. It is causal and has computational complexity that grows linearly with the size of the data. Moreover, we show through real-data examples that it is robust, requiring little in the way of training and able to successfully address the object detection problem for a number of GPR systems operating in a wide range of environments. We do stress here that the algorithm in this paper is intended *only* to find anomalies beneath the GPR array and *not* to solve the far more challenging classification problem. Thus, from a practical perspective our approach will serve well as an efficient “pre-screener” in a larger automatic target detection algorithm suite. Finally, our method is motivated by landmine detection using GPR, however it can also be used in other detection application, such as laser-induced acoustic subsurface objects detection [15].

The paper is organized as follows. Section II discusses the problem formulation and our

method. Section III gives some examples of using the method in different situations. Field data from different radar configurations and test sites are used to show how the algorithm works. Conclusion and direction of future work are given in Section IV.

II. PROBLEM FORMULATION AND ALGORITHM

To begin, we consider a single GPR T/R pairs as shown in Fig. 1(a). After each transmission, the receiver collects an echo for a certain amount of time. Depending on the presence of an object, there are either two or three components in the echo. One is measurement noise, assumed to be white and Gaussian. Another is background, i.e., “nominal” signal observed in object-free regions. The third component is object signal, reflection from a buried object.

For the GPR array shown in Fig. 1(b), assume we have M GPR Transmitter/Receiver (T/R) pairs surveying an area in N steps, the task is to use present and previous array measurement to detect buried mines as the array moves down-track. At each down-track position, we model the array detection problem in a typical hypotheses testing framework [14],

$$H_0 : \quad \text{there is no object,}$$

$$H_1 : \quad \text{there is an object.}$$

The null hypothesis H_0 means that there is no buried object in the field of view of the GPR array, so the total received signal is comprised of nominal background and measurement noise. By nominal background, we mean any portion of the received waveform not sensor noise and not arising from the interaction of the transmitted pulse with the object. Reflection from the air-ground interface is the dominant component of this part of the signal. The alternative hypothesis H_1 indicates that there is buried object so that the received signal consists of nominal background, measurement noise, and an object signal.

In this paper we assume that the nominal background signal has been removed via a

preprocessing stage. The most used background removal methods include casual methods, such as subtraction of a moving average from the observation [16], and non-causal methods, such as subtraction of an ensemble average from the observation [17, 18]. Causal methods use data from previous and present collection, non-causal methods use data from previous and future collection. In this paper, a moving average (MA) filter is used to eliminate the nominal background.

In practice, the receiver collects time-samples of the reflection and stores it as a vector. For convenience, we use vector notation in our discussion, i.e., $\mathbf{y}(m, n)$ is a column vector representing observation of the m th T/R pair at the n th down-track position. The length of $\mathbf{y}(m, n)$ is K , the number of samples in time. Fig. 3 shows the received signal after the nominal background removal.¹ We then have the hypothesis test

$$\begin{aligned} H_0 : \quad \mathbf{y}(m, n) &= \mathbf{v} \\ H_1 : \quad \mathbf{y}(m, n) &= \mathbf{s}(m, n) + \mathbf{v} \end{aligned} \tag{1}$$

where $m = 1, \dots, M$, $n = 1, \dots, N$ are positions of GPR, $\mathbf{s}(m, n)$ is the assumed signal due to presence of buried object, \mathbf{v} is assumed to be a white Gaussian noise with a zero mean, and covariance matrix $\sigma_v^2 \mathbf{I}$, where \mathbf{I} is the identity matrix of size K and independent of (m, n) .

The statistical assumptions about \mathbf{v} are not strictly accurate in describing the noise in a GPR signal. For example the background removal process will not be perfect leaving a component of correlated “clutter” in the data which may or may not possess Gaussian statistics. Despite the mismatch, the use of the additive white Gaussian noise model is useful for a number of reasons. This model allows us to develop an algorithm for object

¹ For the purpose of illustration, in this section we use field data from a buried metal mine to illustrate clearly the concept under consideration. Examples which demonstrate better the utility of our approach on more challenging problems, including buried plastic mines, are given in Section III.

Fig. 3. Signals from four T/R pairs, after background removal, a) pair 1, b) pair 2, c) pair 3, d) pair 4. Unit in time axes is 0.02 ns.

detection which is firmly rooted in Gaussian-based statistical decision theory and which can be generalized in the future for more complex noise processes. Moreover, the complexity of such algorithms is quite low making them well suited for real-world implementation. Finally, test results in Section III from real field data demonstrate that the method is quite effective in detecting objects. Thus, the Gaussian noise model is shown to work in practice. While it may be interesting to explore other, more accurate models for the sensor noise to determine for example what can be gained in terms of performance and what would be lost in terms of computational complexity, such an effort is beyond the scope of the work in this paper.

Based on the previous discussion, after background removal the hypothesis test in (1) may be written as

$$\begin{aligned} H_0 : \quad & \mathbf{y}(m, n) \sim N(\mathbf{0}, \sigma_v^2 \mathbf{I}) \\ H_1 : \quad & \mathbf{y}(m, n) \sim N(\mathbf{s}(m, n), \sigma_v^2 \mathbf{I}), \quad m = 1, \dots, M, \quad n = 1, \dots, N \end{aligned} \quad (2)$$

where the notation $\mathbf{y} \sim N(\bar{\mathbf{x}}, \mathbf{R})$ indicates that \mathbf{y} is distributed as a Gaussian random vector with mean $\bar{\mathbf{x}}$ and covariance matrix \mathbf{R} .

As stated in the Introduction, we take a two-step approach to the processing of $\mathbf{y}(m, n)$. First for each n we use the HANOVA procedure to generate a single test statistic, $Y(n)$, from the data from all T/R pairs. Second, a recursive, sequential detection scheme is employed to process $Y(n)$ as we proceed down track in order to determine where objects are present.

A. Cross-track Processing

We begin by discussing the use of HANOVA to process data in the cross-track direction. HANOVA is a generalized version of analysis of variance (ANOVA). ANOVA is a body of methods to analyze the data with a view to test hypotheses about the effects of one or more factors [19]. To review the basics of ANOVA, we follow the notation established above for the GPR problem and for simplicity assume we have one data vector of size $K \times 1$ from a single T/R pair, $\mathbf{y} \sim N(\mathbf{s}, \sigma^2 \mathbf{I})$ and we wish to test $H_0 : \mathbf{s} = \mathbf{0}$ (i.e., no object) vs. $H_1 : \mathbf{s} \neq \mathbf{0}$ (i.e., an object present)². Standard ANOVA is essentially an “energy detection” scheme [12] where we estimate \mathbf{s} by \mathbf{y} , generate the test statistic $Y = \|\mathbf{y}\|^2$, and compare Y to a threshold, γ . If Y exceeds the threshold, H_1 is chosen, else H_0 is selected. The probability of detection of the standard ANOVA is

$$P_d(H_1|H_1) = Q\left(\frac{\gamma - \frac{\|\mathbf{s}\|^2}{\sigma^2 \sqrt{2K}}}{\sqrt{1 + \frac{2\|\mathbf{s}\|^2}{\sigma^2 K}}}\right) \quad (3)$$

² For notational simplicity, we drop the explicit dependence of all quantities on m and n in this discussion

where γ is the test threshold decided by setting an acceptable probability of false-alarm under H_0 and Q is the complementary cumulative distribution function and is strictly decreasing [20]

$$Q(Y) = \int_{\gamma}^{\infty} P_1(Y) dY. \quad (4)$$

Recently, Fan [12] and Fan and Lin [13], have noted that the performance of ANOVA suffers for problems when the signal of interest is limited to a window of the observation vector. The reason is that a full dimensional test loses its power due to accumulation of stochastic noise. To see why, suppose \mathbf{s} is different from $\mathbf{0}$ only for say the first k_0 samples of the full observation vector. Then on average as $K > k_0$ goes large, $\sum_{k=1}^K [\mathbf{s}]_k^2 / \sigma^2 \sqrt{2K}$ decreases due to the accumulation of zero mean noise samples and the term within the parenthesis of (3) increases, thus reducing P_d . Therefore, for higher probability of detection, we would like to confine the test on a window mostly containing the signal of the observation vector. The window we choose is a box window \mathbf{w} , defined as

$$[\mathbf{w}]_k = \begin{cases} 1, & k = k_1, \dots, k_2 \\ 0, & \text{otherwise} \end{cases} \quad (5)$$

where $1 \leq k_1 < k_2 \leq K$. The k_1 and k_2 are chosen in a preset manner, as discussed later in this section. Multiplying each element in \mathbf{y} by the corresponding element of \mathbf{w} gives the windowed \mathbf{y}_w

$$[\mathbf{y}_w]_k = [\mathbf{y}]_k \times [\mathbf{w}]_k, \quad k = 1, \dots, K. \quad (6)$$

To demonstrate the utility of HANOVA, we test the time-series shown in Fig. 4(a). We choose to test the vector at its full dimension k_1 in (5) is 1 and $k_2 = 1000$, and two windowed sub-dimensions (each containing fewer and fewer noise components) $k_1 = 100$ and $k_2 = 900$,

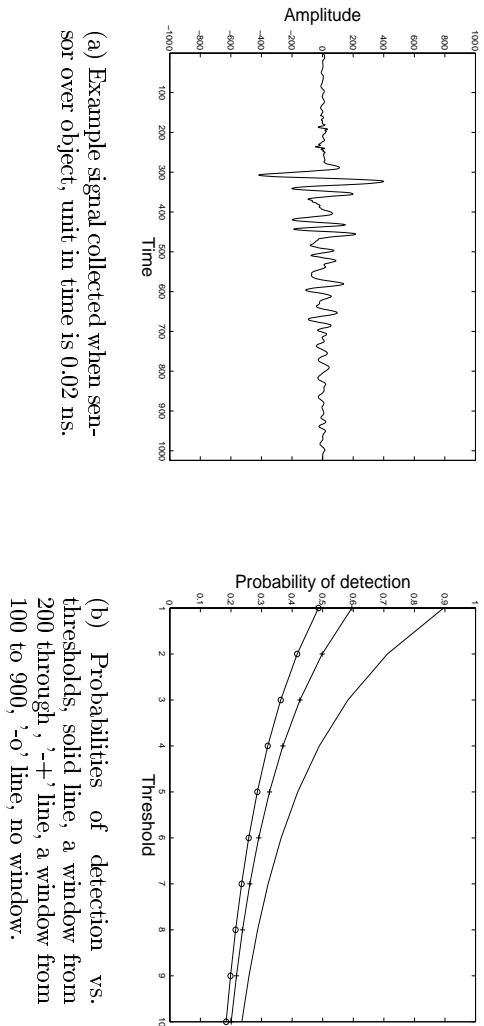

Fig. 4. Motivating example for use of HANOVA rather than ANOVA. (a) displays sample data collected by a GPR when over an object. The transient nature of the relevant portion of the signal is clear. Using this signal, in (b) we display the decreasing detection rates associated with including increasing numbers of “noise” samples in the processing.

and $k_1 = 200$ and $k_2 = 800$. From Fig. 4(b), it is seen that by setting the window properly, higher probability of detection is gained at different levels of detection thresholds, γ in (3). It demonstrates that when signal is not “full-dimensional”, looking for a window of signal-rich sub-dimensions to test will increase the probability of detection.

When the observation is a sequence of high-dimensional vectors whose components are mostly noise, as is the case for our GPR problem, it is desirable to adaptively choose the window to maximize the probability of detection. This kind of method of reducing a full dimensional test to a windowed version is called HANOVA [13]. Fan’s original work was limited to problems in which the first k_0 dimensions are believed to be signal-rich and used in HANOVA, with k_0 found from the data. Here we consider a generalization of Fan’s work to take into account the fact that for the GPR problem the transient signal is significant over a window not generally starting with the first dimension but in the middle of the observation vector. Moreover, this window will vary with (m, n) .

To choose this window we note that (3) indicates that the probability of detection achieves its maximum value when the term inside the parenthesis is minimized. Equally, one wants to maximize the quantity

$$\arg \max_{k_1, k_2} \frac{\sum_{k=k_1}^{k_2} [\mathbf{s}(m, n)]_k^2}{\sigma_v^2 \sqrt{k_2 - k_1 + 1}} - \sqrt{k_2 - k_1 + 1} \quad (7)$$

where $k_1 < k_2$ and $k_1, k_2 \in 1, \dots, K$. The difficulty for us is that in general, the precise structure of \mathbf{s} is not known. Hence, we use the data to form an estimate of \mathbf{s} as follows. Assume we are at the n th stop, then we estimate \mathbf{s} by the mean value of the previous l vectors

$$\hat{\mathbf{y}}(m, n) = \begin{cases} \frac{\sum_{j=1}^n \mathbf{y}(m, j)}{j}, & n = 1, \dots, l \\ \frac{\sum_{j=n-l}^n \mathbf{y}(m, j)}{l}, & n > l \end{cases} \quad (8)$$

where $m = 1, \dots, M$ and the corresponding window $\mathbf{w}(m, n)$ is decided based on $\hat{\mathbf{y}}(m, n)$ as k_1, k_2 are defined by (7). More will be said about choosing a proper l in Appendix A.

Rather than looking for the optimal window by searching over all k_1 - k_2 pairs, we pursue a suboptimal, but more efficient two-stage approach. First, we fix k_1 as 1, incrementally increase k_2 , and stop when (7) is maximized. Thus we determine the end point of the window k_2 . Starting from k_2 , working backward toward the first point, we similarly determine the starting point of the window, k_1 . Both searching steps can be computed in linear complexity, it takes $o(K)$ steps to find the k_2 and $o(k_2)$ steps to find the k_1 ³. In summary the steps for looking for windows at the n th stop of the GPR array are given in Fig. 5.

Having determined the window at the position (m, n) , the next stage of processing is to generate a single detection statistic at stop n . Here we generalize HANOVA to multiple vector observations, via

$$Y(n) = \frac{1}{\sigma_v^2} \sum_{m=1}^M \|\mathbf{y}_w(m, n)\|^2. \quad (10)$$

³ The notation $o(K)$ means that the computational complexity grows slower than or equally fast as K increases.

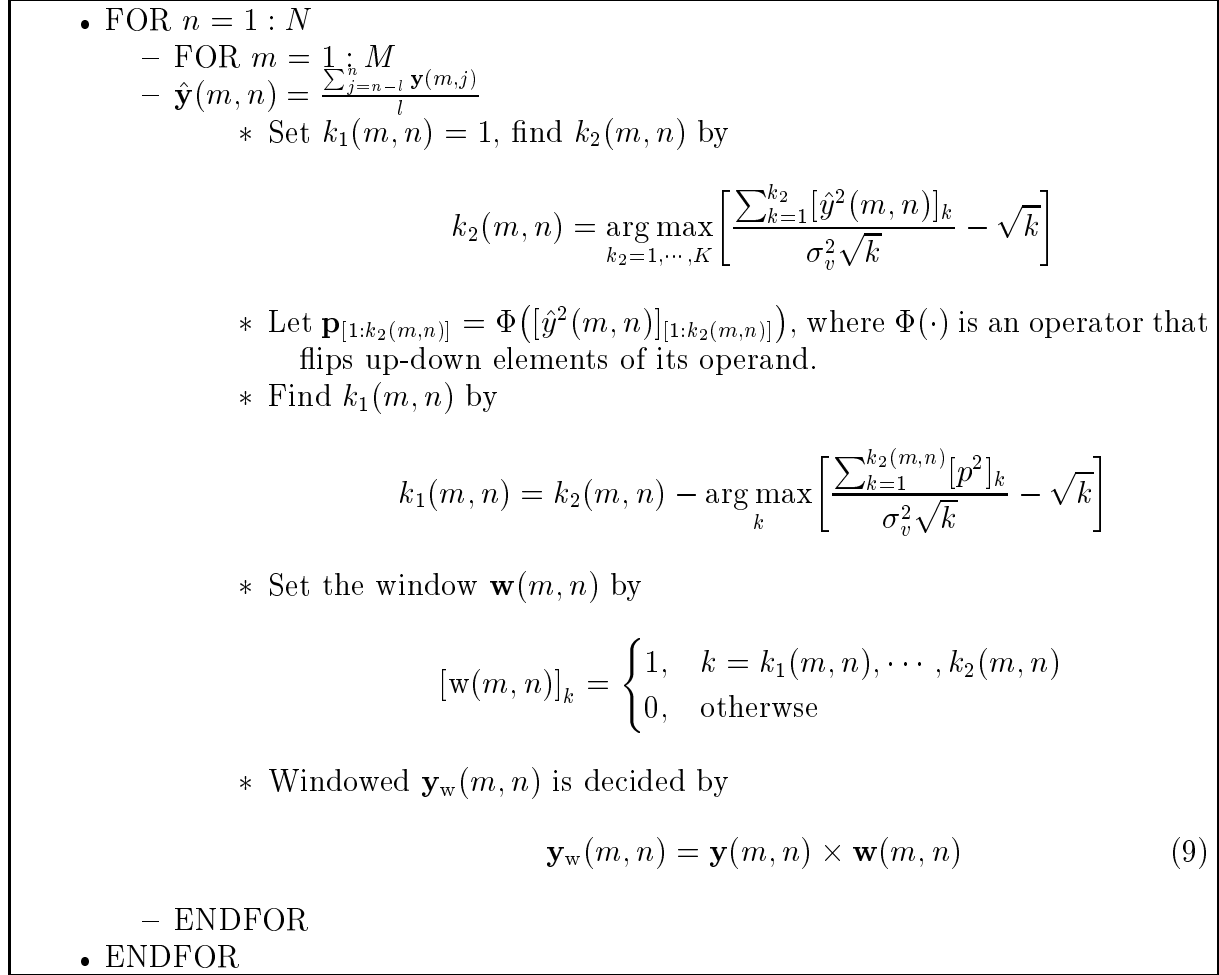

Fig. 5. Steps of deciding window $\mathbf{w}(m, n)$ and $\mathbf{y}_w(m, n)$.

Note $\mathbf{y}_w(m, n)$ can be of different length because of different window applied. Fig. 6(a) shows the result of applying HANOVA to the data in Figure 3. Where the HANOVA output is high, so too is the likelihood of an object being present. Thus in Fig. 6(a), the object is clearly detectable. More examples involving different types of objects will be given in Section III.

B. Down-track Processing

While HANOVA detects statistical significance at one stop of the array, it does not capture the object signal structure seen as the array moves down-track. To improve detection performance, we employ a sequential detection scheme to process $Y(n)$ recursively as n

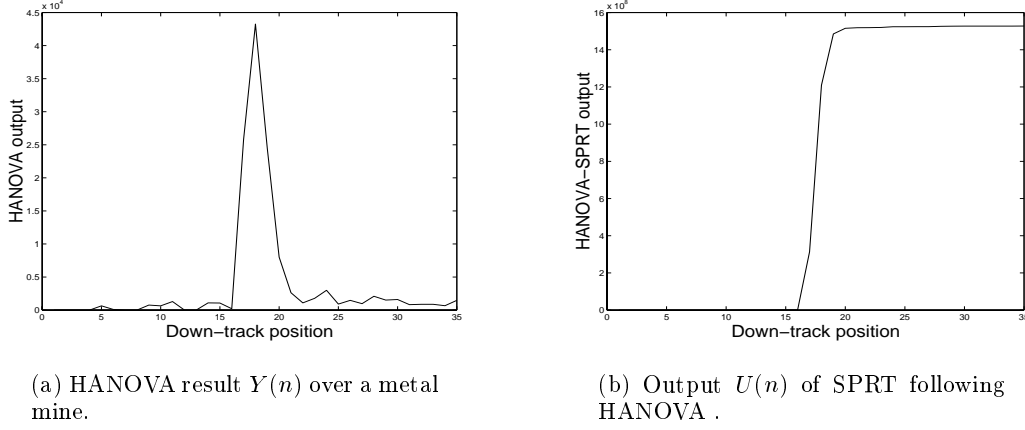

Fig. 6. HANOVA and SPRT processing results for metal mine data shown in Fig. 3

increases in order to identify the transient signal arising from the mine [14,21]. Specification of this sequential probability ratio test (SPRT) begins by noting that under our models $Y(n)$ takes on a χ^2 distribution under both H_0 and H_1 . Standard statistical analysis [12] yields

$$\begin{aligned}
 H_0 : \quad Y(n) &\sim \chi^2_{\sum_{m=1}^M \Delta k(m,n)}(0) \\
 H_1 : \quad Y(n) &\sim \chi^2_{\sum_{m=1}^M \Delta k(m,n)}(\delta^2(n))
 \end{aligned} \tag{11}$$

for $n = 1, \dots, N$ where the notation $x \sim \chi_p^2(\delta^2)$ indicates that the random variable x is distributed according to a χ^2 law of order p and non-centrality parameter δ^2 [20] and $\Delta k(m, n) = k_2(m, n) - k_1(m, n)$ is the length of the (n, m) th window. For the GPR problem it is easy to show that

$$\delta^2(n) = \frac{1}{\sigma_v^2} \sum_{m=1}^M \|\mathbf{s}(m, n) \times \mathbf{w}(m, n)\|^2. \tag{12}$$

For our problem, the length of each window, $\Delta k(m, n)$, is large (on the order of hundreds) and the central limit theorem permits us to approximate the χ^2 distribution using a Gaussian

distribution [20]. We then have

$$\begin{aligned} H_0 : Y(n) &\sim N(\mu_0, \sigma_0^2) \equiv N\left(\sum_{m=1}^M \Delta k(m, n), 2 \sum_{m=1}^M \Delta k(m, n)\right) \\ H_1 : Y(n) &\sim N(\mu_1(n), \sigma_1^2(n)) \equiv N\left(\sum_{m=1}^M \Delta k(m, n) + \delta^2(n), 2 \sum_{m=1}^M \Delta k(m, n) + 4\delta^2(n)\right). \end{aligned} \quad (13)$$

At stop n , the log likelihood ratio for the hypothesis testing problem in (13) is

$$u(n) = \ln \frac{p_n(Y(n))}{p_0(Y(n))}, \quad n = 1, \dots, N \quad (14)$$

where $p_n(Y(n))$ is the PDF of $Y(n)$ evaluated at the n th stop under H_1 and $p_0(Y(n))$ is the PDF of $Y(n)$ evaluated under H_0 . Under H_0 , μ_0 and σ_0^2 are estimated using data from an object-free area. Therefore, for this algorithm, the GPR array must start by collecting data in a calibration region to initialize these variables. Under H_1 , one difficulty with generating $u(n)$ is that $\mu_1(n)$ and $\sigma_1^2(n)$ are typically not known *a priori* since the underlying $\mathbf{s}(m, n)$ are not assumed known. It turns out that we only need to estimate $\mu_1(n)$, and $\sigma_1^2(n)$ can be found from the following relation

$$\begin{aligned} \sigma_1^2(n) &= 2 \sum_{m=1}^M \Delta k(m, n) + 4\delta^2(n) \\ &= 2 \sum_{m=1}^M \Delta k(m, n) + 4 \left[\mu_1(n) - \sum_{m=1}^M \Delta k(m, n) \right] \\ &= 4\mu_1(n) - 2 \sum_{m=1}^M \Delta k(m, n). \end{aligned} \quad (15)$$

At the n th stop, we estimate the mean of $Y(n)$ by its maximum likelihood estimator $\mu_1(n) = Y(n)$.

The *sequential probability ratio test* statistic $U(n)$ is a cumulative sum, changing with the acquisition of each new $u(n)$

$$U(n) = \max(0, U(n-1) + u(n)). \quad (16)$$

- $U(1) = 0$
- FOR $n = 2, \dots, N$
 - $\mu_1(n) = Y(n)$
 - Form $\sigma_1^2(n)$ according to (15)
 - Form $u(n)$ according to (14)
 - $U(n) = \max(0, U(n-1) + u(n))$
 - IF $U(n) > \alpha$, declare object, set $U(n) = 0$, ENDIF
- ENDFOR

Fig. 7. Sequential processing.

Because subsurface object detection is a binary hypothesis testing problem, e.g., we are only interested in knowing whether there is a buried object, the SPRT statistic is bounded from lower bound, zero. When $U(n-1) + u(n)$ is negative, $U(n)$ is reset to zero. For a preset threshold α , the SPRT will make one of two decisions at each n

$$U(n) \geq \alpha \Rightarrow \text{choose } H_1$$

$$U(n) < \alpha \Rightarrow \text{take another observation.}$$

The sequential detection is then essentially a repeated SPRT [22] and summarized in Fig. 7. Fig. 6(b) shows the sequential test statistic when the SPRT is applied to the data in Fig. 6(a). Because the SPRT in (16) has the form of a modified “integrator,” a typical time series for the SPRT statistic takes a step-like form. The larger and sharper the step, the more likely it is that a target is present. At the position where there is an object, the sequential test statistics has a clear upward change again indicating the existence of an object at about position 16.

III. EXAMPLES

In this section we use field data as examples to illustrate the performance of our method. The field data are collected by both single GPR and GPR arrays at different test sites. For each data set, we compare the results from using standard ANOVA, HANOVA, ANOVA

followed by SPRT, and HANOVA followed by SPRT. Comparison indicates that generally HANOVA performs better than ANOVA, and with SPRT, both ANOVA and HANOVA make fewer false-alarms. In other words, HANOVA with SPRT gives the best receiver-operating characteristics, as we shall see later in this section.

At first, we apply our method on data collected by single GPR at different test sites. Some data are taken under relatively favorable condition, while most are from more hostile test sites which involve rough ground surface and other clutter. Fig. 8 compares results of ANOVA and HANOVA on a buried steel object at position 50. For comparison, the outputs of ANOVA and HANOVA are normalized to one. It is observable that while both methods detect the object easily, the HANOVA is better in suppressing noise output where there is no object, e.g., at position 1 through 40 and 60 through 100, Fig. 8(c) and (d). Fig. 9 shows the results from detecting a plastic mine, M19, at position 50. Again, the HANOVA performs better in suppressing noise. At positions 20 through 40, the HANOVA creates a much lower noise level than the ANOVA does. Similarly, the HANOVA produces a cleaner output at the end of the run.

Fig. 10 shows the results of ANOVA and HANOVA in detecting an anti-tank mine, TM62, from a very “noisy” data set. The mine is buried at position 60. Outputs of both HANOVA and ANOVA consist of the correct detection and some false alarms. The HANOVA maintains a better performance than the ANOVA in the sense that, for a given detection threshold, the HANOVA would generally have a smaller number of false-alarms. For the HANOVA, no false alarms will be declared for a threshold greater than 0.5, while for the ANOVA, the threshold must be set above 0.8 to avoid making a wrong decision. Between threshold 0.5 and 0.8, the ANOVA will make two false-alarms while the HANOVA has zero false-alarm.

Fig. 8. Results of a single GPR measurement above a steel object around position 50, a) raw observation, b) observation after nominal background removal, c) ANOVA output, d) HANOVA output. In a) and b), each unit in time axes is 0.02 ns.

Next, by comparing the outputs of the SPRT in the above three examples, we see that sequential processing generally smoothes the output and generates fewer false-alarms than by using ANOVA (or HANOVA) only, Fig. 11. In all three examples, SPRT following HANOVA performs better than SPRT following ANOVA, in the sense that the output is more leveled off at object-free area and the jump at the position of the buried object is sharper.

To study the receiver operating characteristic (ROC) of the method, we test our method on multiple runs of different type of targets. Fig. 12(a) shows the ROC curves of ANOVA and HANOVA to detect metallic objects. The objects include metallic mines such as TM15,

Fig. 9. Comparison between the ANOVA and HANOVA, a) raw data over an M19, anti-tank mine, buried at position 50, b) demeaned data, c) result of the ANOVA over the M19, d) result of the HANOVA.

TM46, and PMN. Fig. 12(b) shows the ROC of ANOVA-SPRT and HANOVA-SPRT. Compared with Fig. 12(a), SPRT improves the performance of both ANOVA and HANOVA. In generating these curves a correct identification of any of the objects was taken to be a “detection” whether or not the object itself was a mine. Indeed, as noted in the Introduction, the algorithm in this paper is intended *only* to detect the presence of objects below the array and not to solve the classification problem. Still, given the “real-world” conditions under which the data were taken, the low false alarm rates here point to the robustness of our approach.

Next, we compare the performance of ANOVA, HANOVA, ANOVA-SPRT, and HANOVA-

Fig. 10. More comparison between the ANOVA and HANOVA, a) raw data over a TM62, anti-tank mine, buried to the side of the track at position 58, b) demeaned data, c) result of the ANOVA, d) result of the HANOVA.

SPRT in detecting plastic mines. The mines are M19, VS-1.6, T72, and C4A1. Fig. 13 shows the ROC curves of the above four methods. It is seen that both the ANOVA-SPRT and HANOVA-SPRT perform better than the ANOVA and HANOVA, respectively.

As another example, we test our method on a different array radar system at another test site. The setup of the GPR array is shown in Fig. 14. There is one transmitter in this system. In front of the transmitter, four receivers are positioned in a 2×2 pattern. Above the transmitter and the receivers there is a hyperbolic reflection plate, it is set so that the transmitter is at the focal point of the reflection plate. The array moves on a linear track

to collect data. At each step, the transmitter sends a spherical wave to the reflection plate and after reflection, the sphere wave becomes plane wave. The four receivers then collect reflection of this plane wave from the ground. The system has the advantage of generating plane wave and points it forward to reduce ground reflection. Fig. 15 displays collected data from the two front receivers at the Dedham test site of Northeastern University and the corresponding signal after background removal. In an area of 58 m², there are 12 buried landmines of different types, such as M19, PMN, VS-2.2, and so on. Using our method we are able to detect all 12 mines with a few false-alarms, Fig. 16. The results are similar to those obtained by a single GPR. For a detection rate above 90%, the HANOVA has a significantly smaller number of false-alarm.

IV. SUMMARY

In this paper, we have proposed a sequential, high-dimensional ANOVA to process GPR returns. The method is tested on real data and has a relaxed requirement on the physical model used in the processing routine. The method is on-line implementable and has a linear computational load. The method works in two stages: first it looks for statistically significant difference from array observations, second, it applies a sequential detection as new data are obtained. HANOVA is powerful in the sense of maximizing probability of detecting statistically significant difference among sub-dimensions of a full vector of observations. Sequential detection recursively processes the result of the HANOVA and enables real-time processing as new data are collected. We have demonstrated the performance of this technique on samples of field data.

Future research will focus on classification and localization. Classification consists of two steps. First, a feature extraction scheme is applied on reflected signals to generate intermediate result, second, the output from feature extraction is fed into a Bayesian classifier

to make the classification. Localization is based on optimized frequency-wavenumber (F-K) migration. F-K migration is an inversion method that back-propagates wavefield from the ground surface to subsurface and construct an image of subsurface reflectivity. Regular F-K migration is well modeled for seismic signal processing. Though GPR signal is different from seismic signal, F-K migration can still work very well in processing GPR signals. Nonetheless, improvement in terms of resolution and accuracy can be achieved by considering optimization in F-K migration. In our future work, an optimization method will be used to improve the F-K migration.

APPENDIX

I. WINDOW SELECTION IN HANOVA

Ideally, we want to find a window that is sensitive to the presence of a signal and provides little response in the test statistic when there is noise only. But these two requirements are often in conflict with each other. From (8), we can change the order l of the MA process to control the window we use. The smaller is l , the more sensitive the window is to the presence of signal and strong noise. On the other hand, the larger is l , the more robust will the statistic be to noise, which translates into a smaller probability of false-alarm. But a large l reduces sensitivity of the HANOVA to signal. Fig. 17 shows the effect of l on window selection and the corresponding HANOVA results. Three different l are used, i.e., $l = 1, 4, 9$. In the data, there are three mine objects, two metal mines at the position 110 and 170. A weak mine object is at position 25. For comparison, we normalize the HANOVA outputs in each case by its maximum value, which corresponds to the strong metal mine buried at position 110. Fig. 17(a) and (b) show the window chosen by a MA of order 1 and the resulting HANOVA output. The two strong objects can be detected at a threshold of 0.7, the weak object can only be found at a threshold of 0.2. Fig. 17(c) shows the window

chosen by a MA of order 4. The window oscillates much less than the window in Fig. 17(a). From the HANOVA result, Fig. 17(d), we can find all the three objects at a threshold of 0.3. Increasing the order of MA process can make the results worse, Fig. 17(e) and (f). A large window reduces the sensitivity of the HANOVA to signal and actually makes detection more difficult. Now the weak object at position 25 can not be detected at a threshold greater than 0.3. As a guideline, we find that MA processes of order between 3 and 10 yield good windows both in sensitivity to signal and robustness to noise. This selection is affected by the step-size of the array. An array moving at small step-size will allow an MA process of large l in selecting windows, and vice versa.

Baseband Wiener Filter Processing for Mine Detection from Scanned Laser Induced Acoustic Data

Northeastern University, Boston, MA.

ABSTRACT

We consider the problems of detecting, localizing, and characterizing the shapes of buried mines from acoustic transducer data. A multipath model is used to describe the contributions in the data from fields scattered both by the ground as well as the object. By identifying the parameters in the model, we can successfully solve the target identification problem. Unfortunately, the narrow band and bandpass characteristics of the transducer in our system prevent a straightforward application of a Wiener filter as a means of extracting these parameters. Because of the bandpass nature of the transducer it is necessary to develop a base-banding procedure as a preprocessing stage for the Wiener filter. Due to the very narrow bandwidth, a detect and subtract method is constructed to extract the weak signal arising from the buried object which otherwise is drowned out in the sidelobes generated by the processing of the ground bounce. We demonstrate the utility of our approach on real experimental data collected at Northeastern University.

Keywords: Mine detection, laser induced acoustic scanner, Wiener filter

1. INTRODUCTION

The problem of detecting and localizing buried mines from observation of reflected radiation has received considerable attention in recent years. In this paper, we consider a statistical signal processing approach to solving such problems given data collected using a scanning laser-based acoustic sensor developed in [1]. The experimental system is shown in Fig. 1. The transmitter sends a laser pulse into the ground where an unknown target is buried. An acoustic wave is generated by the sand as it is heated by laser. Part of this acoustic wave is reflected by the ground and seen by the acoustic transducer. The other part is transmitted into the earth and reflected by a landmine. Thus the received signal will be the mixture of reflected waves from both the ground and the target. This procedure is repeated on a regular basis as the apparatus scans a 2D grid. The objective of the processing is the localization and characterization of the buried object given this collection of time traces.

Because the propagation and scattering of acoustic waves through the earth is a highly complex physical process even when the constitutive parameters of the medium are known, it would be quite difficult to employ sophisticated inverse scattering type methods to image the subsurface. Thus, in this paper we consider a simplified model for describing the data which lends itself to accurate yet tractable information extraction algorithms. We assume that the problem can be described using a so-called *multipath model* commonly employed in the field of communications² wherein the received signal at location i of the scan, $r_i(n)$, can be expressed as

$$r_i(n) = s(n) * h_i(n) + w(n) \quad (1)$$

Figure 1. Experimental system

where $s(n)$ is taken to be a nominal template signal, $w(n)$ is additive noise and $*$ denotes convolution. The multipath channel impulse response, $h_i(n)$, characterizes the structure of the reflection from the ground and the mine when the sensing system is at location i and is written as

$$h_i(n) = \sum_{j=1}^{N_i} \alpha_{i,j} \delta(n - \tau_{i,j}) \quad (2)$$

with N_i the number of paths seen at location i . In this work, N_i is taken to be one or two depending on whether only the ground bounce is seen in the receiver ($N_i = 1$) or if one observes both the ground bounce as well as a response from the buried object ($N_i = 2$). The quantities $\tau_{i,j}$ are the time delays associated with each path and the $\alpha_{i,j}$ are amplitude reduction factors caused by the propagation and scattering processes.

The goal of the processing then is the determination of the multipath parameters, $\{N_i, \alpha_{i,j}, \tau_{i,j}\}$ for each position of the sensor. As we discuss in § 3, examination of these quantities can be of great use in localizing and characterizing the shape of a buried object. From a processing perspective then, the challenging feature of this problem is the detection of the multipath parameters. This is a common statistical signal processing problem and for which various solution methods have been proposed including generalized cross correlation,³ Wiener-type filtering,⁴ and nonlinear estimation techniques.⁵ In this paper, we focus our attention on Wiener filtering processing due to its simplicity and strong performance for the problem at hand.

2. DETECTION METHOD

The Wiener filter solution for a discrete time channel identification problem given by (2) is⁴:

$$\hat{H}(e^{j\omega}) = \frac{R(e^{j\omega})S^*(e^{j\omega})}{|S(e^{j\omega})|^2 + \epsilon} \quad (3)$$

where $\hat{H}(e^{j\omega})$, $R(e^{j\omega})$ and $S(e^{j\omega})$ are the discrete-time Fourier transforms (DTFT) of $\hat{h}(n)$, $r(n)$ and $s(n)$ respectively, ϵ is the variance of the channel distribution, and a hat over a variable indicates estimated quantity. The desired multipath parameters can then be determined by taking the inverse DTFT of (3) to obtain $\hat{h}(n)$ and finding the peaks. The locations of the peaks provide estimates of the delay parameters and the amplitudes of the peaks yield the α 's. There are however three difficulties that need to be addressed before applying the Wiener filter to our problem:

- The received signal in our system is bandpass. As is discussed at length in § 2.1 this introduces a number of phase shifts which impact the performance of a straightforward Wiener filter implementation.
- The ability to clearly distinguish the peaks in \hat{h} requires that the data be broadband. Unfortunately, the transducer in our system has a very narrow bandwidth so $\hat{h}(n)$ will display large side-lobes and a broad main-lobe. The delay and amplitude estimation problem becomes much more difficult in this case especially since the second path (indicating the presence of an object) will be highly attenuated with a delay quite close to that of the ground bounce.
- The template $s(n)$ for our problem is unknown while the above processing assumes it is given. The precise structure of the template signal depends on the nature of the transmitter and receiver as well as the detailed physics of the propagation problems. For none of these quantities do we currently have accurate models.

To solve this problem we examine two approaches. First, we will determine $s(n)$ empirically by taking it to be the signal received from a known no-mine location. That is, the observed ground path will represent the template. Then all other traces will be processed based on this template. Second, we explore methods for adaptively updating the template as the sensor scans to combat the spatial variability of the template and reduce the effects of additive noise.

These three problems will be addressed in the following three subsections respectively.

2.1. Baseband processing with Wiener filter

Because the transducer acts as a bandpass filter, the Wiener filter output is bandpass with a non-zero carrier. Since there is normally a phase shift between the baseband Wiener filter output and this carrier, the peak location of the bandpass Wiener filter output will generally differ from that of the baseband case. More importantly, there is also a phase shift between the reflected waves from the ground and the buried object. In this case, the bandpass signal can not be used directly as a template for the Wiener filter because the reflected wave of the second path is no longer a scaled and delayed version of the first. This fact makes direct use of the Wiener filter in (3) highly inaccurate. However, this problem can be solved by the following baseband processing.

Dropping the explicit dependence on i , the position of the sensor, the bandpass signal can be written as $s(n) = s_c(n) \cos(\omega_0 n + \phi) - s_s(n) \sin(\omega_0 n + \phi)$, where s_c and s_s are the in-phase and quadrature parts of s respectively. Denote the baseband expression of $s(n)$ as $s_b(n) = s_c(n) + js_s(n)$. Assuming there are

only two paths in the channel, we have $r(n) = \alpha_1 s(n - \tau_1) + \alpha_2 s(n - \tau_2) + w(n)$, where α_1 and α_2 are real and $w(n)$ is additive Gaussian noise. After substitution, we have

$$r(n) = \sum_{j=1}^{N_i} \alpha_j s_c(n - \tau_j) \cos(\omega_0(n - \tau_j) + \phi_j) + \alpha_j s_s(n - \tau_j) \sin(\omega_0(n - \tau_j) + \phi_j) + w(n) \quad (4)$$

The signal $r(n)$ then is down converted to baseband by multiplying by $\cos(\omega_0 n)$ and $\sin(\omega_0 n)$ respectively. After some algebra, it can be shown that at baseband,

$$r_b(n) = \sum_{j=1}^{N_i} \alpha_j \exp(j\phi'_j) s_b(n - \tau_j) + w_b(n) \quad (5)$$

where $w_b(n)$ is the baseband expression for $w(n)$ and is complex. Thus, it can be seen that by using $s_b(n)$ as a template, path information such as time delay τ , amplitude α and phase shift ϕ' can be detected by a Wiener filter which is employed at baseband. Following this algorithm, our baseband Wiener filtering procession can be implemented as shown in Fig. 2.

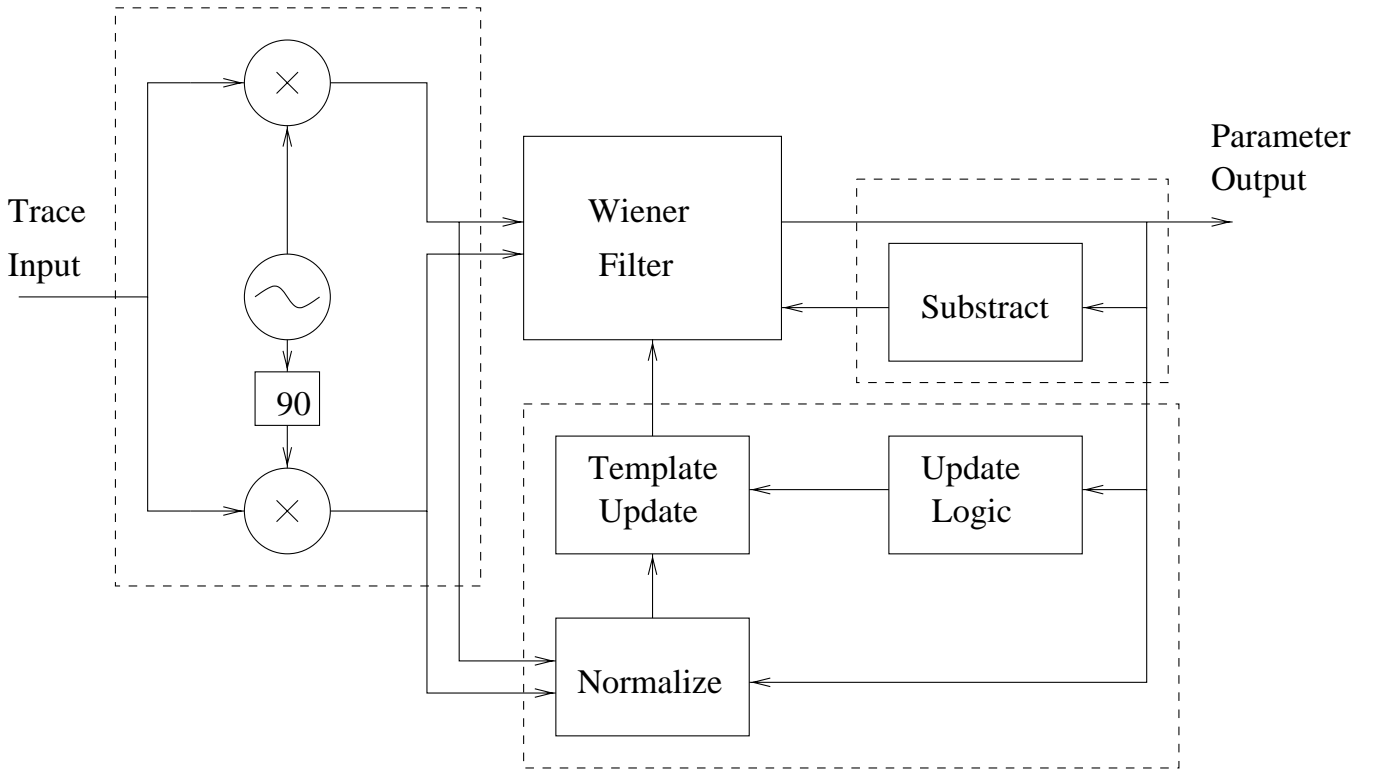

Figure 2. Baseband Wiener filter processing

2.2. Template Determination

The next problem we address is the determination of the template signal $s_b(t)$. We begin by using a fixed template obtained as the trace at a known no-mine location. By doing this, it is assumed that the noise level is not very high which is valid for our system. While the assumption of a fixed template may be

accurate over some limited spatial region, the changing characteristics of ground (temperature, moisture, material composition, etc.), imply that one should consider methods for adaptively updating the template. Thus, the problem at hand is how to decide the template for a new trace before we do the processing. To address this difficulty, first we assume that the system is slowly space-varying system, which implies the template at a location will be highly correlated with that of its neighbors. Thus we may predict the new template based on the previous templates.

One issue of concern here is that we update the template using only data from positions in which there is no buried object. While one could extract templates from neighboring scans for which a mine is present, the utility of such a procedure is heavily dependent on the accuracy of the estimated multipath parameters. While the experiments in § 3 demonstrate that we can determine roughly the location and shape of the buried object, at this point in time, the parameter estimates are not sufficiently accurate for template extraction. Thus, we prefer to take an approach where, at each location of the sensor, we first determine whether or not there is a buried object present. This determination is made by examining the estimate of the amplitude coefficient associated with the second path. If this estimate is above a given threshold, we say that a mine is present, otherwise we assume there is no object at this position. A couple of remarks are in order concerning this process:

1. At the current time, the threshold is determined assuming we have a rough idea as to the size of the second-path amplitude coefficient for the class of buried objects of interest. Clearly, a key area of future research is the adaptive determination of this quantity as the sensor scans the region.
2. Given knowledge of the second-path amplitude, we currently set the mine/no-mine threshold relatively low to ensure that few traces associated with the presence of a mine are used in the updating procedure. This low threshold does cause some cases where we should update the template but do not because we mistakenly say that a mine is present. We have found empirically that such “mistakes” have little impact on the overall results of our processing as the template itself generally changes quite slowly so that a small number of missed updates cause little degradation in performance.

Finally our updating algorithm is

$$s_{new}(n) = (1 - \beta)s_{old}(n) + \beta r'(n) \quad (6)$$

where $s_{new}(n)$ is the new template, $s_{old}(n)$ is the old template, β is updating factor and $r'(n)$ is a normalized version of current trace $r(n)$ with $r'(n) = r(n - \tau_1)/\alpha_1$. The received current trace cannot be used directly because the ground is normally not flat. The ground-reflected trace will have a different arrival time thus causing error if added directly. Further, the power of the template needs to be fixed so that the detected amplitude information of the second path can be employed to make a decision at both the updating stage and the post-detection stage. Moreover, by averaging the signals using (6) this algorithm is seen to be capable of alleviating the effects of additive noise.

So far what has been achieved is a Wiener filter output which contains all the information of the channel while the particular characteristic of template are largely eliminated. The next question we want to answer is how to extract channel information from this output. This issue is highly nontrivial when considering the extremely narrow bandwidth of the received signal (see Fig. 3). As discussed in the next section, we consider a detect and subtract method for solving this problem.

2.3. Detect and Subtract

The acoustic transducer used in our system has a very narrow bandwidth (Fig. 3). Thus, in the time domain, all the spikes (i.e. multipath components) in the channel response are “smeared out” which makes

Figure 3. Frequency spectrum of received signal

the distinction of closely separated paths very difficult. More problematic, it also introduces large side lobes at the output of the Wiener filter which makes weak paths vanished in the side lobes of a strong path. Unfortunately, the amplitude of the desired second path (coming from the mine) is much smaller than that of main path (coming from the ground) in our system. Thus the second path is very difficult to detect from the original Wiener filter's large-rippled output. Figs. 4(a) and (c) are typical traces obtained over a no-mine location and a mine location respectively. Clearly, they are very similar and the second path can not be detected directly.

Our method to overcome this problem is as follows. First we extract the information (amplitude, time delay and phase shift) from the ground-reflected path. Due to the strength of this signal, this process is generally quite accurate. Next, rather than continuing by looking for the second path from this original Wiener filter output, we use our estimated parameters to mathematically subtract the ground bounce portion of the signal from the current time trace. By using this modified trace as input to a new Wiener filter, it is then much easier to determine the parameters of the signal component coming from the buried object. In Figs. 4(b) and (d) we show the Wiener filter output after subtraction of the first path for Figs. 4(a) and (c) respectively. It can be seen that the second path is clear in Fig. 4(d) while the second path in Fig. 4(b) will be eliminated due to its small amplitude.

2.4. Mine Detection with Post Processing

By applying the above methods, we get estimates of the amplitude, time delay and phase shift of the ground-reflected wave (first or main path) and the target-reflected wave (second path). The issue now is how best to use the information of the second path to decide if there is a mine and determine the mine's contour and depth in the sand.

Note that no matter whether there is a mine, the second path parameters are always estimated. However it can be seen from the results that the mine's information can be identified by noticing the fact that at positions where a mine is present: (a) the amplitudes of the second path will be relatively large and (b) the time delay of the second path will be pretty close (flat target surface) or vary slowly (non-flat

(a) No 2nd path, before DAS

(b) No 2nd path, after DAS

(c) With 2nd path, before DAS

(d) With 2nd path, after DAS

Figure 4. Output of Wiener filter

target surface). Based on these observation, simple post processing is employed by checking the amplitude of second path and comparing the time delay with its neighbors. First, for locations with the largest second path amplitudes, we say there is a mine. Then we reduce the amplitude threshold and examine the locations which are adjacent to the currently-detected mine-locations. If their delays are close enough (a delay threshold is used here), we say these adjacent locations are also mine-locations. This process is then repeated until a predetermined amplitude threshold is reached at which point we stop. As was the case with the template updating process, the value of this lower amplitude limit is determined under the assumption that we have a rough idea as to the second-path amplitude coefficient for the class of object under consideration.

3. RESULTS

The sand box is grided into 25x15 unit squares and a half hockey puck is buried horizontally. The results of the fixed template method are shown in Fig. 5, (a) is the ground delay (relative to the initial template which is chosen to be (1,1) location), from which we can see that the ground is not flat as assumed and has a small slope. Fig. 5(b) and (c) are the amplitude and time delay of detected second paths respectively. It can be seen that the amplitudes of the second path when a mine is present are relatively larger than those of no-mine locations and the time delays for mine locations are pretty close to each other (due to flat upper surface of the target). After post-detection processing, the mine's support is shown in Fig. 5(d).

The updating template method is also employed with several different updating factors, β in (6). It is found that when β is large (eg. 0.8 or 1.0), the system is sensitive to the detection error and the performance is worse. If β is 0 then we have the non-adaptive processing scheme. We have experimentally determined that an updating factor of 0.2 is found to be a good choice and its results are shown in Fig. 6. We can see that ground delay is similar to what we had before but the amplitude and time delay of the second path are much clearer. Finally, the detected mine's support is shown in Fig. 6(d). Relative to the fixed template case, we see that the holes have been filled and the outliers entirely suppressed.

Fig. 7 shows the results of the updating template method (with $\beta = 0.2$) when two rectangular targets are buried in the sand. As can be seen, these two objects can also be detected clearly.

4. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented an approach for the detection and localization of buried mines from acoustic transducer data via parameter estimation using a multipath propagation model. Since the received signal is bandpass, a baseband Wiener filter is introduced to solve the problem of phase shifts among the multipath components in the signal. Due to the extremely narrow bandwidth of the transducer, distinct multipath spikes are smeared out and large side lobes are generated in the output of the Wiener filter. A detection and subtraction method then is employed to deal with this bandwidth problem. Both fixed and adaptive template methods are considered in this paper. It can be seen from the result that the later works better by properly choosing the update factor.

The above processing is based on a linear multipath model assumption. Specifically, the characteristics of acoustic wave propagation are entirely omitted to simplify the analysis and computation. Thus the detection performance is expected to be better if the model can be improved to include more specific features of the acoustic wave properties. In particular, we conjecture that there is a third signal component caused by reflection of the input signal from the bottom of the mine. Our current processing methods however are insufficient to pull this very weak signal from the data. The solution may lie on the improvement of channel and noise model but also on the more powerful parameter estimation methods. All told, we consider the following topics to be of great interest for future work

1. Propagation model improvement.
2. Noise characteristic modeling.
3. Adaptive and robust methods for determining the thresholds in the template updating and post detection processing stages.
4. Performance analysis for all detection and estimation stages of our approach.
5. Post detection algorithm modification to further sharpen the boundaries of the object.

ABSTRACT

We consider the problem of detecting and localizing buried landmines from a ground penetrating radar (GPR) array. A simplified, ray-optics-based physical model for time domain GPR returns is presented. Under this model in the absence of an object from the field of view of the array, there exist well defined symmetries in the structure of the radar returns. In particular, for a bistatic system composed of one length M transmit array and a second length M array of receivers, we identify M subsets of signals from the M^2 total transmitter/receiver pairs such that the mean value of the signals within each subset should be the same when no object is present. This relationship then forms the basis for a modified Hotelling's T^2 -test to detect the presence of objects when there is noise in the signal. Simulation results demonstrate the validity of these methods.

1. INTRODUCTION

Mines kill or maim hundreds of people every week, mostly innocent and defenseless civilians. Among the various demining methods developed in recent years, ground penetrating radar (GPR) holds substantial promise because of its sensitivity to non-metallic, plastic objects which traditional metal detectors are largely incapable of finding. Nevertheless, using GPR to detect and localize mines is both difficult and complex. One key problem is the rejection of interference caused by the signal arising from scatter off the air-earth interface. Both the magnitude of the ground bounce and its timing are such that they can easily swamp the relatively small signal arising from the interaction of the transmitted GPR waveform with the buried mine. To help overcome this difficulty, we consider the use of a GPR array to provide a richer and more diverse set of data thereby making accurate detection and localization possible in circumstances where a single GPR is unable to perform well.

In this paper we discuss a method to detect mines which exploits both the physics of the problem as well as the geometry of the array system. We assume that the GPR array is deployed as shown in Fig. 3 with one linear array of transmitters and a second array of receivers both traveling down a track. As described in Section 3, the geometric symmetry inherent in this configuration introduces a “statistical symmetry” in the received signals. In particular, this symmetry is preserved precisely when there is no mine. On the other hand, the presence of a mine will break this symmetry and therefore provide information as to the existence of an object. Based on this relationship, we develop a statistical test of homogeneity to ascertain the presence of an object in the field of view of the array.

The organization of this paper is as follows. Section 2 introduces the physical model of GPR signals and the configuration of the GPR array. In Section 3 we present the detection algorithm, using a modified

form of Hotelling's T^2 -test. Examples are given in Section 4 to demonstrate validity of the algorithm. Section 5 summarizes present work and points out future research direction.

2. PHYSICAL MODEL AND PROBLEM FORMULATION

2.1. A Single GPR System

To detect and localize mines, a ground penetrating radar array is implemented. Fig. 1 shows a typical single GPR system with the signals it generates.¹ In this paper we assume a simplified model where the signal seen by the receiver is composed of at most two components. The first signal is the reflected signal from the ground and is always present in the data. The second component (if it exists) is the reflected contribution from an object in the field of view of the array.

Figure 1. Schematic drawing of a single GPR, transmitter and receiver.

The received signal, $\phi(t)$, is taken to be the sum of delayed and attenuated versions of two “template” signals indicating the nominal behavior of the ground bounce signal and the nominal behavior of a signal arising from scattering from a mine. Mathematically we have

$$\phi(t) = a\psi_g(t - \tau_g) + b\psi_m(t - \tau_m) \quad (1)$$

where ψ_g and ψ_m are the nominal ground bounce and mine reflected signal, a and b are attenuation factors, τ_g is the delay of the ground reflection, and τ_m is the delay of the mine signal. Note that if no mine is present, ϕ is just equal to the first term of (1).

To find the delays and the attenuation factors we assume that the propagation of the signal from the transmitter to the receiver can be described using a ray-optics-type model shown in Fig. 1. That is, the ground bounce is composed of signal reflected from the interface at the specular point midway between the transmitter and receiver while the four-part path of the mine component of the signal can be determined via the judicious use of Snell's law.

To begin, the τ_g and τ_m are determined by the travel time of two-way paths and can be calculated as

$$\text{Delay} = \frac{\text{2-way path length}}{\text{velocity of the wave}}. \quad (2)$$

To find τ_g and τ_m , we need to locate reflecting point and refracting point shown in Fig. 2. Let media 1 be air and media 2 be soil, with electric permittivity ϵ_0 and ϵ_1 , respectively, Fig. 2.(a), the reflecting point on the boundary between two points (x_1, y_1) and (x_2, y_1) in media 1 is simply the mid-point $(x_4, 0)$, where $x_4 = \frac{x_1 + x_2}{2}$.

Figure 2. Geometries for determining (a) the reflecting point and (b) the refracting point, $\epsilon_1 > \epsilon_0$.

For the refracting point, according to Snell's law, for a source located at (x_1, y_1) in media 1 and target at (x_3, y_3) in media 2, the refracted ray from source to target must intersect the boundary at a point $(x_5, 0)$, Fig. 2.(b), such that²

$$\frac{Re\{\epsilon_1\}}{\epsilon_0} = \frac{\frac{(x_1 - x_5)^2}{(x_1 - x_5)^2 + y_1^2}}{\frac{(x_3 - x_5)^2}{(x_3 - x_5)^2 + y_3^2}}. \quad (3)$$

Solution of this quartic equation has four roots. By Fermat's principle, which states that of all possible paths joining two given points on a wave path, the wave path has actual least travel time, we can discard three physically impossible roots and retain the true refracting point. Once the reflecting point and the refracting point are established, the delay τ_g and τ_m can be found as,

$$\tau_g = 2 \frac{\sqrt{(x_1 - x_4)^2 + y_1^2}}{c} \quad (4)$$

$$\tau_m = 2 \frac{\sqrt{(x_1 - x_5)^2 + y_1^2}}{c} + 2 \frac{\sqrt{(x_3 - x_5)^2 + y_3^2}}{c/Re\sqrt{\epsilon_1}} \quad (5)$$

where c is the speed of light in air and $\frac{c}{Re\sqrt{\epsilon_1}}$ is the speed of the wave in soil.

In addition to the time delays, the received signal $\phi(t)$ has an amplitude reduction caused by propagation through the soil as well as geometric spreading as it traverses both the air and the earth. In soil, the wave attenuates exponentially with the distance it travels, $e^{-\alpha_s d}$. The quantity α_s is the attenuation constant of the soil which is related to the conductivity and permittivity of the medium³ while d is the distance the wave travels in the earth. We assume geometric spreading results in an inverse path length amplitude reduction. Referring to the setup of Fig. 2, then we have the overall amplitude reduction factors given by

$$a = \frac{1}{2\sqrt{(x_1 - x_4)^2 + y_1^2}} \quad \text{and} \quad b = \left(\frac{e^{-\alpha_s \sqrt{(x_3 - x_5)^2 + y_3^2}}}{\sqrt{(x_1 - x_5)^2 + y_1^2} + \sqrt{(x_3 - x_5)^2 + y_3^2}} \right)^2.$$

2.2. GPR Array

In this work, the GPR array is assumed to consist of M pairs of transmitters and receivers. Data are collected by the GPR array as it travels step by step down track, Fig. 3. At each stop of the array, M^2 signals (time-traces) are collected; one for each transmitter/receiver pair.

Figure 3. Array of GPR, moves in x-direction(down-track).

Using the model developed in the previous section and assuming that the GPR array is at its k -th stop, the signal seen at receiver j due to input from transmitter i is written as

$$\phi_{ij}^k(t) = a_{ij}\psi_g(t - \tau_{g,ij}) + b_{ij}^k\psi_m(t - \tau_{m,ij}^k), \quad i, j = 1, \dots, M, \quad k = 1, \dots, K. \quad (6)$$

Note that a and τ_g do not depend on k , the down-track GPR array position. This is easy to understand because the ground-reflected signal only depends on the relative position of transmitter and receiver*. To simplify matters, in the future we use the following shorthand

$$g_{ij}(t) = a_{ij}\psi_g(t - \tau_{g,ij}) \quad s_{ij}^k(t) = b_{ij}^k\psi_m(t - \tau_{m,ij}^k).$$

Each $\phi_{ij}(t)$ is densely sampled P times over a time interval. The interval is chosen to be long enough to embrace both ground bounce and mine signal. When no ambiguity will arise, we refer to the vector of samples, $\underline{\phi}_{ij}^k$, rather than the temporal signal, $\phi_{ij}^k(t)$ with a similar interpretation holding for \underline{g}_{ij} and \underline{s}_{ij}^k . Note $\underline{\phi}_{ij}^k$, \underline{g}_{ij} , and \underline{s}_{ij}^k are column vectors of size P .

For a given location of the GPR array, to detect mines, we carry out a binary hypothesis test. Under the null hypothesis, H_0 , the received signal $\underline{\phi}_{ij}^k$ is comprised of ground bounce \underline{g}_{ij} plus measurement noise, which is assumed to be a white Gaussian vector, $\underline{w} \sim N(0, \sigma^2 \mathbf{I})$. Under the alternate hypothesis, H_1 , $\underline{\phi}_{ij}^k$ consists of ground bounce, noise, and mine signal, \underline{s}_{ij}^k . Mathematically we have

$$\begin{aligned} H_0^k : \quad & \underline{\phi}_{ij}^k = \underline{g}_{ij} + \underline{w} \\ H_1^k : \quad & \underline{\phi}_{ij}^k = \underline{g}_{ij} + \underline{s}_{ij}^k + \underline{w}. \end{aligned} \quad (7)$$

Our processing method is based on the observation that under H_0 , the M^2 received signal should display certain symmetries, as illustrated by Fig. 4. For example if no mine is present then $\underline{\phi}_{12}$ should be “statistically equal” to $\underline{\phi}_{21}$, $\underline{\phi}_{23}$, $\underline{\phi}_{32}$, $\underline{\phi}_{34}$, and $\underline{\phi}_{43}$ because the ground bounce in each case depends only on the relative spacing of the sensors which is identical for these six pairs. Similarly, $\underline{\phi}_{13}$ should be statistically equal to $\underline{\phi}_{31}$, and so on. By “statistically equal” we mean that any variations in these signal are caused by random sensor noise. In other words, signals from these sets will, on average, possess the same means with some variability (variance) caused by the noise. Thus statistical tests designed to determine homogeneity of a population (i.e. equality of mean vectors) can be used to test whether an object is present (lack of homogeneity) or absent (all the data vectors are about the same). Finally, for the M^2 received signals it is not hard to show that there are only M sets of statistically different signals because of this symmetry. Note the M sets of signals are not of equal size, some sets consist of more signals than the others.

*Here we are assuming that the ground is locally flat over the extent of the sensing system. Extension of the results in this work to smoothly changing ground is an area of current work.

Figure 4. Symmetry of GPR signals, 4 different path lengths are shown in solid line, dashed line, dashed-dot line, and dot line.

3. INFORMATION EXTRACTION ALGORITHM

From the above discussion, we know that if a mine is present, the symmetry of received signals will be disrupted. Therefore, to detect mines, we can look for asymmetry of received signals. Basically, our approach is to sequentially detect any changes in the means of the received signals. For the purpose of illustration, we use $M = 4$ pairs of transmitter and receiver. At each stop k of the GPR array, we then have 4 sets of statistically different signals, $S_1 = \{\phi_{11}^k, \phi_{22}^k, \phi_{33}^k, \phi_{44}^k\}$, $S_2 = \{\phi_{12}^k, \phi_{21}^k, \phi_{23}^k, \phi_{32}^k, \phi_{34}^k, \phi_{43}^k\}$, $S_3 = \{\phi_{13}^k, \phi_{31}^k, \phi_{24}^k, \phi_{42}^k\}$, and $S_4 = \{\phi_{14}^k, \phi_{41}^k\}$.

3.1. Homogeneity Test of Single Set

Here we discuss the homogeneity test of a single set, say $S_1 = \{\phi_{11}^k, \phi_{22}^k, \phi_{33}^k, \phi_{44}^k\}$. We consider the acceptance test of the hypothesis

$$H_0: \underline{\phi}_{ii}^k \text{ in the set are from same multivariate Gaussian distribution, with equal and known covariance matrices, and identical, unknown means, } i = 1, \dots, 4.$$

Because the test is identically the same at each stop k for the remainder of this subsection we drop the k notation.

As the problem currently stands, we do not assume that the ground bounce signals are known. In fact, a simple transformation of the data allows us to perform the test without ever having to know the ground bounces or estimate them. To see this, we begin by forming the collection of all pairwise differences of the signals within the set under consideration. For S_1 we get the set D_1 defined as

$$D_1 = \left\{ \phi_{11} - \phi_{22}, \phi_{11} - \phi_{33}, \phi_{11} - \phi_{44}, \phi_{22} - \phi_{33}, \phi_{22} - \phi_{44}, \phi_{33} - \phi_{44} \right\} \equiv \{\underline{\delta}_1, \underline{\delta}_2, \underline{\delta}_3, \underline{\delta}_4, \underline{\delta}_5, \underline{\delta}_6\}.$$

Testing H_0 using the original set of $\underline{\phi}_{ii}$ signals then is equivalent to testing the following hypothesis using the $\underline{\delta}_n$ vectors:

$$H'_0: \underline{\delta}_n \text{ in the set are from same multivariate Gaussian distribution, with equal and known covariance matrices and means equal to zero}$$

To test this equality of means, we carry out a Hotelling's T^2 -test.⁴ As described more fully in [5], this test amounts to the following comparison

$$\xi_1 = \sum_{n=1}^6 \frac{1}{2} \underline{\delta}_n^T \mathbf{R}^{-1} \underline{\delta}_n \leqslant threshold \quad (8)$$

with $\mathbf{R}(= \sigma^2 \mathbf{I})$ is the covariance matrix of the measurement noise and *threshold* is chosen to ensure an *a priori* specified probability of false acceptance. The hypothesis is accepted if the left hand side is less than or equal to *threshold* and rejected otherwise. Noting that \mathbf{R} is diagonal, we write ξ_1 as

$$\xi_1 = \frac{1}{2\sigma^2} \Phi_1^T \mathbf{A}_1 \Phi_1 = \frac{1}{2\sigma^2} \begin{bmatrix} \underline{\phi}_1^T & \underline{\phi}_2^T & \underline{\phi}_3^T & \underline{\phi}_4^T \end{bmatrix} \begin{bmatrix} 3\mathbf{I} & -\mathbf{I} & -\mathbf{I} & -\mathbf{I} \\ -\mathbf{I} & 3\mathbf{I} & -\mathbf{I} & -\mathbf{I} \\ -\mathbf{I} & -\mathbf{I} & 3\mathbf{I} & -\mathbf{I} \\ -\mathbf{I} & -\mathbf{I} & -\mathbf{I} & 3\mathbf{I} \end{bmatrix} \begin{bmatrix} \underline{\phi}_1 \\ \underline{\phi}_2 \\ \underline{\phi}_3 \\ \underline{\phi}_4 \end{bmatrix}. \quad (9)$$

For a set S_i of size N_i , it is easy to show that \mathbf{A}_i is an $N_i \times N_i$ block matrix. Its block diagonal elements are $(N_i - 1)\mathbf{I}_{P \times P}$ and the off diagonal elements are $-\mathbf{I}_{P \times P}$.

3.2. Homogeneity Test of Multiple Sets

For the application of interest in this paper, we have multiple sets (four for our sample system) for which we wish to test homogeneity. Here we adopt a simple, generalized form of the T^2 test in which the four ξ_i 's are weighted and added to yield one final test statistic,

$$\xi = \xi_1 \eta_1 + \xi_2 \eta_2 + \xi_3 \eta_3 + \xi_4 \eta_4. \quad (10)$$

The η_i are weight factors, defined by

$$\eta_i = \frac{1}{l_i} \left(\sum_{j=1}^4 l_j^{-1} \right)^{-1} \quad (11)$$

where l_j are the path lengths of ground bounces for set S_j . More will be said about this weight factor in Section 3.3. Stacking all the 16 signals ϕ_{ij} to form a long column vector, we obtain a new vector

$$\Phi^T = [\Phi_1^T \ \Phi_2^T \ \Phi_3^T \ \Phi_4^T]$$

and

$$\xi = \frac{1}{2\sigma^2} \Phi^T \mathbf{A} \Phi = \frac{1}{2\sigma^2} \begin{bmatrix} \Phi_1^T & \Phi_2^T & \Phi_3^T & \Phi_4^T \end{bmatrix} \begin{bmatrix} \mathbf{A}_1 \eta_1 & 0 & 0 & 0 \\ 0 & \mathbf{A}_2 \eta_2 & 0 & 0 \\ 0 & 0 & \mathbf{A}_3 \eta_3 & 0 \\ 0 & 0 & 0 & \mathbf{A}_4 \eta_4 \end{bmatrix} \begin{bmatrix} \Phi_1 \\ \Phi_2 \\ \Phi_3 \\ \Phi_4 \end{bmatrix}. \quad (12)$$

Matrix \mathbf{A} is a block diagonal matrix. Obviously, \mathbf{A} is symmetric. Note \mathbf{A} is positive semidefinite by its buildup. According to Mathai,⁶ the first two moments of ξ are given by,

$$\begin{aligned} \mu_\xi &= (6\eta_1 + 15\eta_2 + 6\eta_3 + \eta_4)P \\ \sigma_\xi^2 &= (24\eta_1^2 + 90\eta_2^2 + 24\eta_3^2 + 2\eta_4^2)P.^\dagger \end{aligned} \quad (13)$$

It has been shown that ξ asymptotically has a Gaussian distribution⁶ for large NP , i.e., $\xi \sim N(\mu_\xi, \sigma_\xi^2)$. The generalized T^2 -test amounts to $\xi \leq \alpha$ where α is the threshold chosen to ensure an *a priori* specified probability P_{fa} of false acceptance. The α is determined by

$$P_{fa} = \int_{\alpha}^{\infty} \frac{1}{\sqrt{2\pi\sigma_\xi^2}} e^{-\frac{(\xi-\mu_\xi)^2}{2\sigma_\xi^2}} d\xi. \quad (14)$$

3.3. Sequential Detection

Now we consider the actual GPR array operation as the array moves down-track. At each stop k , we calculate a corresponding ξ^k . When there is no mine in the field of view of the array, we record ξ^k only. That is, $\nu^k = \xi^k$ under hypothesis H_0 . When there is a mine, the mine signal \underline{s}_{ij}^k adds to the ground bounce. Passing \underline{s}_{ij}^k to the generalized Hotelling's T^2 -test produces an output signal, denoted by ζ^k . So the problem is to detect signal ζ^k , given the observed signal sequence ν^k and known “noise” ξ^k , using the additive noise model $\nu^k = \xi^k + \zeta^k$ under the alternate hypothesis H_1 . Though ζ^k is unknown and changes with k , it is always *positive* because of the very nature of quadratic form of the generalized T^2 -test. Fig. 5 shows separate ξ_i^k and $\xi_i^k + \zeta_i^k$. Signals on the left side of Fig. 5 are typical “noise” sequences, taken from four different sets of transmitter-receiver combinations. Signals on the right side are “noise” and mine signals, corresponding to the respective sets of transmitter-receiver combinations. It is seen that ζ_i^k are much weaker in set S_3 and S_4 . This observation can be explained by the increased attenuation associated with the longer distances the mine signals in sets S_3 and S_4 travel. For this reason, we introduced the weight factors in Eq. 11.

When the mine is buried deep, the mine signal attenuates exponentially as explained in Section 2.1. Detecting this unknown low power signal can be aided quite a bit using sequential detection methods which retain information from previous scans to improve the SNR. We therefore employ a sequential detector as the GPR array moves down track. At each stop k , the detector makes one of two decisions⁷: (1) Hypothesis H_0 is true, no mine signal is present, (2) Reject H_0 . Because ζ^k causes a positive displacement of the mean of ν^k , we choose a running average of ν^k as a statistical test^{8,9}

$$g^k = \frac{1}{N} \sum_{j=k-N+1}^k \nu^j, \quad k = N, N+1, \dots, K \quad (15)$$

and make a decision by checking $g^k \leq \beta$ where β is a threshold. At each stop k , g^k is compared to the threshold to make a declaration of mine presence. Fig. 6 illustrates relationship between threshold settings and declaration of mine presence as the GPR arrays move down-track. Each filled dot indicates a location of the array where we say that a mine is present. Such a declaration is made when g^k is above the threshold for consecutive 5 stops of k . A lower threshold allows us to make early declaration of mine. The disadvantage is a high false-acceptance rate. The false-acceptance probability P_{fa} equals the probability under hypothesis H_0 that the g^k crosses the threshold. The detection probability P_d equals to $1 - P_{fa}$. By virtue of the generalized T^2 -test, ν^k are statistically independent. Hence, g^k has the Gaussian distribution, $N(\mu_\xi, \frac{1}{N}\sigma_\xi^2)$. Thus, in principle, for a given P_{fa} , β can be determined similarly as in Eq. 14.

[†]See appendix

Figure 5. First row of figures corresponds to the T^2 statistic for set S_1 , the left figure is “noise” only, the right figure has both “noise” and mine reflected signal, second row of figures corresponds to set S_2 , third row of figures corresponds to set S_3 , and, fourth row of figures corresponds to set S_4 .

Figure 6. Detection results versus prescribed false alarm probability, P_{fa} . Note that lower P_{fa} results in slower detection while a higher allowable false alarm rate allows for detection prior to the array passing over the mine.

4. EXAMPLES

In this section we consider some examples of the above procedure. Monte-Carlo runs were used to determine the probability of detection and probability of false-alarm for various noise levels and depth of buried mines. In this work, the signal to interference plus noise ratio is defined as

$$\text{SINR} = 10 \log_{10} \frac{\underline{s}^T \underline{s}}{\underline{g}^T \underline{g} + P\sigma^2}. \quad (16)$$

In all cases, we generate synthetic data with an object located around the 50th stops of the GPR array and buried 10 cm underground. The GPR array is composed of four pairs of transmitters and receivers evenly spaced along a baseline width of 80 cm. A transmitter and its corresponding receiver (e.g. transmitter 1 and receiver 1) are 20 cm apart. The GPR array is 40 cm above the ground. For simplicity we assume that the nominal ground bounce and mine-bounce signal take the form of a second derivative of a Gaussian shown in Fig. 7(a). Current work in our group is aimed at developing more sophisticated models for these signals. Fig. 7(b) and (c) show the received signals of two pairs of T/R combinations. Because of the domination of the ground bounce, it is difficult to see any mine signature. Even after pairwise subtraction, the mine signal can hardly be observed in Fig. 7(d). But the generalized T^2 -test can pick up this difference and declare a mine.

Fig. 8(a) shows the receiver operating characteristics of detecting a mine buried 10 cm underground. Fig. 8(b) shows two ROC's for mines buried at different depth under the same noise power. Because of the fast attenuation in soil, the deeper buried mine has a significantly smaller SINR thereby leading to the degradation in performance.

5. CONCLUSIONS AND FUTURE WORK

In this paper, we discuss a statistical approach to detect mines using a GPR array. Exploiting the geometric symmetry of GPR array setting, we have looked into tests for statistical homogeneity of GPR returns as a tool for performing detection. Basically, by treating the received signal as a multivariate Gaussian distribution we test its statistical homogeneity using a generalized, sequential Hotelling's T^2 -test.

Future work will take into consideration of rough ground-air interface and time-delay estimation to actually localize detected mines. An assumption of this work is that the soil conditions are known. Sensitivity analysis involving mismatch in soil parameters will be valuable to apply this method to realistic scenario. Moreover, the additive white Gaussian noise mode will be lifted as we explore issues associated with the modeling of clutter, the incorporation of these models into our processing, and the development of test which are robust (or invariant) to uncertainty in these models.

6. APPENDIX

From Mathai's⁶ work, for $\mathbf{X} \sim \mathbf{N}(\mu, \Sigma)$, the first two moments of quadratic $\mathbf{X}^T \mathbf{A} \mathbf{X}$ can be found by

$$\begin{aligned} E[\xi] &= \text{tr}(\mathbf{A}\Sigma) + \underline{\mu}^T \mathbf{A} \underline{\mu} \\ \text{Var}[\xi] &= 2\text{tr}(\mathbf{A}\Sigma)^2 + 4\underline{\mu}^T \mathbf{A} \Sigma \mathbf{A} \underline{\mu}. \end{aligned} \quad (17)$$

For the generalized T^2 -test, we have

$$\underline{\mu}^T = \left[\underline{\mu}_{11}^T, \dots, \underline{\mu}_{44}^T, \underline{\mu}_{12}^T, \dots, \underline{\mu}_{34}^T, \underline{\mu}_{13}^T, \dots, \underline{\mu}_{24}^T, \underline{\mu}_{14}^T, \underline{\mu}_{41}^T \right] \quad (18)$$

(a) Received signal, the second order derivative of a Gaussian.

(b) Time trace of ϕ_{11}

(c) Time trace of ϕ_{22}

(d) Difference of time traces, $\phi_{11} - \phi_{22}$,
SINR = -11 dB.

Figure 7. Received signal and time traces.

Figure 8. Receiver operating characteristics.

where

$$\begin{aligned}
 \underline{\mu}_{11} = \dots = \underline{\mu}_{44} &\equiv \underline{\mu}^{(1)} & \underline{\mu}_{12} = \dots = \underline{\mu}_{34} &\equiv \underline{\mu}^{(2)} \\
 \underline{\mu}_{13} = \dots = \underline{\mu}_{24} &\equiv \underline{\mu}^{(3)} & \underline{\mu}_{14} = \underline{\mu}_{41} &\equiv \underline{\mu}^{(3)}.
 \end{aligned} \tag{19}$$

Next, we note that $4\underline{\mu}^T \mathbf{A} \Sigma \mathbf{A} \underline{\mu} = 0$ under the condition of Eq. 19,

$$4\underline{\mu}^T \mathbf{A} \Sigma \mathbf{A} \underline{\mu} = 4 \sum_{i=1}^4 \underbrace{\begin{bmatrix} \underline{\mu}^{(i)T} & \dots & \underline{\mu}^{(i)T} \end{bmatrix}}_{N_i} \mathbf{A}_i \Sigma \mathbf{A}_i \begin{bmatrix} \underline{\mu}^{(i)} \\ \vdots \\ \underline{\mu}^{(i)} \end{bmatrix} \tag{20}$$

where

$$\begin{bmatrix} \underline{\mu}^{(i)T} & \dots & \underline{\mu}^{(i)T} \end{bmatrix} \mathbf{A}_i = 0 \tag{21}$$

because of the semidefiniteness of \mathbf{A}_i . Similarly, $\underline{\mu}^T \mathbf{A} \underline{\mu} = 0$. The mean of ξ is then given by $\frac{1}{2\sigma^2} [tr(\mathbf{A} \Sigma)]$. For $\mathbf{A} = \text{block diag} \{ \mathbf{A}_1 \eta_1, \mathbf{A}_2 \eta_2, \mathbf{A}_3 \eta_3, \mathbf{A}_4 \eta_4 \}$ we have

$$E[\xi] = \frac{1}{2\sigma^2} tr(\mathbf{A} \Sigma) = \frac{1}{2} \sum_{i=1}^4 N_i (N_i - 1) P \eta_i. \tag{22}$$

Additionally $\mathbf{A} \mathbf{A} = \text{block diag} \{ \mathbf{A}_1 \mathbf{A}_1 \eta_1^2, \mathbf{A}_2 \mathbf{A}_2 \eta_2^2, \mathbf{A}_3 \mathbf{A}_3 \eta_3^2, \mathbf{A}_4 \mathbf{A}_4 \eta_4^2 \}$ where

$$\mathbf{A}_i \mathbf{A}_i = \begin{bmatrix} (N_i^2 - N_i) \mathbf{I} & -N_i \mathbf{I} & \dots & -N_i \mathbf{I} \\ -N_i \mathbf{I} & (N_i^2 - N_i) \mathbf{I} & \dots & -N_i \mathbf{I} \\ \dots & \dots & \ddots & \dots \\ -N_i \mathbf{I} & -N_i \mathbf{I} & \dots & (N_i^2 - N_i) \mathbf{I} \end{bmatrix}. \tag{23}$$

Here \mathbf{I} is of size $P \times P$ and \mathbf{A}_i is of size $N_i P \times N_i P$. We then have

$$tr(\mathbf{A}_i)^2 = (N_i^2 - N_i)N_i P \quad tr(\mathbf{A})^2 = \sum_{i=1}^4 tr(\mathbf{A}_i)\eta_i^2 = \sum_{i=1}^4 (N_i^2 - N_i)N_i P \eta_i^2.$$

so that $Var[\xi] = \frac{1}{4\sigma^4} 2tr(\mathbf{A}\Sigma)^2 = \frac{1}{2} \sum_{i=1}^4 (N_i^2 - N_i)N_i P \eta_i^2$.

ABSTRACT

The problem of mine localization and characterization from electromagnetic induction data is addressed. We consider processing techniques based on an inductive sensor model originally proposed by Das et. al in [2]. Given this model we examine estimation-theoretic methods for determining an object's center, its orientation, and scattering characteristics (as defined by a spectrum of low order multipole moments) from low frequency spectroscopic data obtained over a grid of spatial locations. Under this model, the data are linear functions of the multipole moment spectra and non-linearly related to object's location and rotation angles. An estimation procedure based on a low-dimensional non-linear optimization routine for the determination of the object center and rotation angles is employed with a linear least squares inversion method used to estimate the multipole moment spectra. Examples are provided for ellipsoidal objects.

1. INTRODUCTION

Electromagnetic induction (EMI) systems represent one of the more common sensing technologies for the detection and localization of buried metallic objects including landmines and unexploded ordinance. While many systems, such as the EM61, operate essentially in the time domain using pulsed induction principals, there has been significant interest recently in the use of swept frequency measurements to perform so-called electromagnetic induction spectroscopy (EMIS). Indeed, work in [1] indicates that data taken over a band from tens of hertz to tens of kilohertz convey information not only about presence of absence of an object but also about object shape, size, orientation, and material characteristics; i.e. such data can in principle be used to perform object characterization.

In this paper, we consider the development of a tractable, physical model to describe an EMIS system and associated processing methods to extract from EMIS data information regarding the location, orientation and structure of a buried object. In Section 2, we describe a generalized form of an EMIS forward model based on the work of Das *et. al.*² Assuming that the incident EMI field is uniform over the support of the object, the model approximates the scattering properties of the object in terms of multipole moment spectra (MMS) which can be used to easily determine the fields observed by the EMI receiver. From an inversion perspective, the idea motivating the work in this paper is that successful estimation of these moment spectra can form the basis for object classification and identification. Also, we note that, unlike general finite element, boundary element, or finite difference type scattering models, the one considered here is particularly well suited for the processing tasks at hand because it is parameterized directly in terms of the quantities of interest: the MMS, the co-ordinates of the object center, and the three rotation angles used to define the orientation of the scatterer relative to a global, Cartesian frame.

Given this model, in Section 3, we describe an algorithm designed to extract this information from EMIS data. Under this model, the data are linearly related to the multipole moment spectra and non-linear

functions of the object location and rotation angles. This functional form is exploited in the construction of an estimation procedure based on a low-dimensional non-linear optimization routine required for the determination of the object center and rotation angles (six variables in all). Embedded within this routine is an associated regularized, linear least squares inversion procedure which determines the estimates of the MMS.

Examples demonstrating the performance of this approach are provided in Section 4. They show the simulation results for the sphere and the spheroid object. Finally, in Section 5, we provide conclusions and indicate future work in this effort.

2. PROBLEM FORMULATION AND PHYSICAL MODEL USED

In this paper we consider an extension of a physical model for EMI proposed in [2] describing the scattering of low frequency electromagnetic radiation by spherical or spheroidal objects of known conductivity and permeability. As seen in Fig. 1 the transmitters and receivers are taken to be square coils (not necessarily co-located) with sides of length $2A$. The target center is located at $r_0 = (x_0, y_0, z_0)$ in the $x - y - z$ coordinate system. For the problems of interest in this work the effects of the low conductivity ground typically can be ignored² so that the entire sensor system is taken to reside in free space.

The physical model is based on the assumption that scattering characteristics of the object of interest can be approximated using a low order multipole model. The electromagnetic force EMF, s , induced in a single turn receive coil by an object at r_0 in response to the field setup by a single loop transmitting coil is given as:

$$s = \frac{i\omega\mu_0\beta_0}{I} g^T \Lambda f \quad (1)$$

where g is a 3×1 vector holding the x , y , and z components of the magnetic field produced at r_0 by a current I flowing in the receive coil, g^T indicates the transpose of g , f is the same as g but for the transmitting coil, ω is the operating frequency, $i = \sqrt{-1}$, and μ_0 is the permeability of free space. As described in Appendix A of [2], the vectors g and f are functions only of the relative positions of the object, the receiver, and the transmitter.

The tensor $\beta_0\Lambda$, defines the multipole scattering characteristics of the object. Here Λ is the normalized polarizability tensor, and $\beta_0 = 3\frac{\mu_r-1}{\mu_r+2}$ is the sensitivity factor for a sphere of relative permeability μ_r . In this work we consider targets to be well modeled as ellipsoids. In the event that the target's axes are parallel to those of a global Cartesian co-ordinate system Λ can be represented as

$$\Lambda = \begin{bmatrix} \lambda_1 & & \\ & \lambda_2 & \\ & & \lambda_3 \end{bmatrix}. \quad (2)$$

The three frequency dependent λ 's (here referred to as moment spectra) each are associated with one of the principal axes of the ellipsoid. For a sphere, all three are identical and closed form expressions can be found for all orders of multipoles.¹ In [2], scattering from spheroids was considered. In such cases, two of the λ 's are the same, and closed form expressions for their dipole moment structure can only be found in the case of $\omega = 0$. More recently, the work in [3] indicates how one might employ multiple poles in the complex frequency plane to accurately model the scattering process for arbitrary objects. Generally, the problem of determining the moment spectra given the axis lengths and material of the object is an open problem and one which we are currently pursuing. Here we assume that such a correspondence can be found and concentrate instead on the estimation of Λ from a given set of data.

In the event that the ellipsoid is rotated relative to the global co-ordinate system, it is necessary to mathematically express the components of g and f in the frame of the ellipsoid as follows. The field vectors

Figure 1. One sensor comprising sensor coils and target object.

f and g are assumed to be expressed in a global Cartesian co-ordinate system $x - y - z$. A second system $x''' - y''' - z'''$, whose axes coincide with the ellipsoid axes can be found by doing the following rotations. It is first rotated through the angle of ϕ about the z -axis. We obtain the new system $x' - y' - z'$. Next the new system is rotated about y' -axis through the angle of θ , resulting in another system $x'' - y'' - z''$. To complete the transformation, the axes are rotated about x'' through the angle of ψ , and we find the last system $x''' - y''' - z'''$, coinciding with the ellipsoid axes. All rotations are shown in Fig. 2. This sequence of transformations is described by the rotation matrix,

$$R = \begin{bmatrix} \cos \theta \cos \phi & \cos \theta \sin \phi & -\sin \theta \\ -\cos \psi \sin \phi + \sin \phi \sin \theta \cos \phi & \cos \psi \cos \phi + \sin \phi \sin \theta \sin \phi & \sin \phi \cos \theta \\ \sin \psi \sin \phi + \cos \psi \sin \theta \cos \phi & -\sin \psi \cos \phi + \cos \phi \sin \theta \sin \phi & \cos \phi \cos \theta \end{bmatrix}. \quad (3)$$

The matrix R is incorporated into the model as follows

$$s = \frac{i\omega\mu_0\beta_0}{I} g^T R^T \Lambda R f \quad (4)$$

where the vector Rf represents the components of the transmitted field in the co-ordinates of the rotated ellipsoid with an analogous interpretation for Rg .

In this work, we are concerned with processing methods based on multi-frequency data obtained from multiple transmitter/receiver locations. Assuming we collect M frequency samples from each of N combinations of transmitters and receivers then we can write the k th frequency sample at the n th position as

$$y_{n,k} = \frac{i\omega_k\mu_0\beta_0}{I} g_n^T R^T \Lambda_k R f_n + w_{n,k} \quad (5)$$

where $w_{n,k}$ is measurement noise. From this data set, our goal is to determine the position, the orientation, and the moment spectra of the buried object.

Figure 2. Angle transformations about three coordinate axes.

3. INFORMATION EXTRACTION ALGORITHM

The model developed in the previous section is particularly well suited to the processing task at hand. First, the position of the target appears only in the vectors g and f and the orientation angles are seen in the matrix R . While the data are non-linear functions of these variables (six in all) the analytical nature of the model makes determination of these quantities relatively straightforward using a non-linear optimization routine. More importantly, the shape and electrical characteristics of the object are encoded in the moment spectra λ_i which are linearly related to the data. Thus, determination of these large vectors (three complex valued unknowns per frequency) reduces to a linear least squares problem the solution of which can be obtained in closed form. In this section, we provide a more detailed description of how these observations are exploited in the design of an efficient processing scheme.

First of all, we manipulate the model to a form that is more suitable for processing. Because $\lambda_i(\omega)$ $i = 1, 2, 3$ is a complex quantity in general, so is $y_{n,k}$. Thus, after separating the data into into real and imaginary parts, we make explicit the linear dependence of the data on the multipole moments as follows

$$\begin{bmatrix} y_{n,k}^R \\ y_{n,k}^I \end{bmatrix} = \underbrace{\begin{bmatrix} a_n^R & 0 \\ 0 & a_n^I \end{bmatrix}}_{A_n} \lambda_k + \begin{bmatrix} w_{n,k}^R \\ w_{n,k}^I \end{bmatrix} \quad (6)$$

$$\lambda_k = [\lambda_{1,k}^R \ \lambda_{2,k}^R \ \lambda_{3,k}^R \ \lambda_{1,k}^I \ \lambda_{2,k}^I \ \lambda_{3,k}^I]^T \quad (7)$$

where superscript R indicates real part and superscript I indicates imaginary part. The a_n^R and a_n^I are 1×3 vectors depending on (a) r_0 , (b) the locations of the transmitter and receiver, and (c) the rotation angles, $\alpha = [\theta \ \psi \ \phi]$. These vectors can be obtained from the f 's, R , and g 's after some straightforward

algebra. Finally, the vector λ_k holds the real and imaginary parts of the samples of the three multipole moment spectra for the ellipsoid at frequency ω_k .

Stacking the data from all transmitter-receiver pairs for all frequencies gives the discretized data model:

$$y = A(r_o, \alpha)\lambda + n. \quad (8)$$

For M frequencies $A = I_M \otimes A_1$ where I_N is the $N \times N$ identity matrix, \otimes denotes the Kronecker product and A_1 is the block diagonal matrix obtained from all the A_n 's. Note that if we collect data from a total of N transmitter/receiver pairs then A_i is a $2N$ by 6 matrix and A is $2NM \times 6M$. Finally, we take the noise vector, w , to be zero mean, independent identically distributed Gaussian random variables with variance σ^2 .

Eq. (8) is used in a penalized least squares approach to determine the location of the object, r_o , the orientation angles, α and multiple moments, λ . Estimates of these quantities, denoted as \hat{r}_o , $\hat{\alpha}$, and $\hat{\lambda}$ respectively, are defined as those values which minimize the following cost function:

$$C(r_o, \alpha, \lambda) = \|y - A(r_o, \lambda)\lambda\|_{K^{-1}}^2 + \sum_{i=1}^3 \beta_i \|L_i \lambda\|_2^2. \quad (9)$$

In (9), $K = \sigma^2 I$ is the noise covariance matrix, $\|x\|_A \equiv x^T A x$, and the L_i are used to regularize the problem by enforcing smoothness in the spectra of the multipole moment estimates. Specifically, L_i is built such that

$$\|L_i \lambda\|_2^2 = \sum_{m \in \{R, I\}} \sum_{k=1}^{M-1} (\lambda_{i,k+1}^m - \lambda_{i,k}^m)^2. \quad (10)$$

The regularization parameters β_i in (9) are used to determine the tradeoff in the reconstruction between the two terms in the cost function. The first terms enforces fidelity to the data while the second ensures smooth spectra. By providing for up to three such parameters, we allow for flexibility in adapting the processing structure to the problem at hand. For example, in the case that we knew we were looking for spherical objects then all three λ_i function would be the same and we would require only one β . For spheroidal objects, where two of the axes are the same, only two β_i and λ_i are required: one for the major and one for the minor axis. Finally, we note that in general, the on-line determination of β_i is a well-studied, non-trivial issue beyond the scope of this paper.⁴⁻⁶ For simplicity, in the examples in Section 4, we assume that the β_i are known.

To minimize the cost function, we note first that because (9) is quadratic with respect to λ , $\hat{\lambda}$ can be explicitly stated in terms of α and r_o via

$$\hat{\lambda} = \left(A^T K^{-1} A + \sum_{i=1}^3 \beta_i L_i^T L_i \right)^{-1} A^T K^{-1} y \equiv Q(r_o, \alpha) y \quad (11)$$

so that we can write:

$$\hat{r}_o, \hat{\alpha} = \arg \min_{r_o, \alpha} C(r_o, \alpha, Q(r_o, \alpha) y) \quad (12)$$

$$\hat{\lambda} = Q(\hat{r}_o, \hat{\alpha}) y. \quad (13)$$

In our experiments we have found that C is generally quite well behaved with respect to the location parameters but exhibits many local minima in terms of the orientation angles. Thus, we have adopted the following strategy for first determining rough estimates of r_o and α and then refining these quantities. We

begin by imposing a coarse grid on the three dimensional space of all permitted orientation angles. For each α -value in the grid, a 3D non-linear least squares solver is used to find the optimal r_0 . We use that α values with the smallest overall cost and the associated estimate of r_0 for that cell to initialize a full 6D non-linear least squares scheme to find the final values of $\hat{\alpha}$ and \hat{r}_0 . Using these values, we construct $\hat{\lambda}$ according to (13).

4. EXAMPLES

In this section, the performance of the estimation approach is demonstrated and analyzed under two mine shapes. We simulate data taken on a 10×10 grid of 100 cm^2 pixels by a monostatic transmit/receive system comprised of square coils 5 cm on a side. Ten frequencies logarithmically spaced between 0 and 4.3 KHz are used. One corner of the grid is taken to be $(0,0) \text{ m}$ while the opposite is at $(1,1) \text{ m}$.

As a first example, we consider a spherical mine located at $(x_0, y_0, z_0) = (0.50, 0.50, .10) \text{ m}^*$, and with radius 5 cm . The medium as well as the object are taken to be non-ferrous and the conductivity of the sphere is 10^6 S/m . We assume that the sphere's response can be modeled as a dipole and we use the results of [1] to compute the dipole moment spectrum (DMS). The real and imaginary parts of this spectrum are shown as a solid line in Fig. 3. Because the sphere is rotationally invariant, there is no need to estimate the rotation angles so the problem here reduces to determining the location and the DMS. To demonstrate the performance of our approach, we perform 10 Monte Carlo simulations at a signal to noise ratio of 20 dB . In this case, the sample mean of the estimated object center is $(0.5000, 0.4998, 0.0993) \text{ m}$ with a standard deviation of $\pm(0.0003, 0.0004, 0.0030) \text{ m}$. In Fig. 3 the dotted lines show the sample mean of the estimated DMS with associated error bars. We see from these results that the approach is highly accurate both in terms of estimating the position as well as the moment spectrum.

Figure 3. The real and imaginary part of estimated and real moment spectra of sphere mine for $\beta = 0.0001$.

*Increasing depth here corresponds to increasing z

As a second example, we consider a spheroidal object[†] again located at $(x_0, y_0, z_0) = (0.50, 0.50, .10)\text{m}$ and which has been rotated using $\phi = 0.75$ radians and $\psi = 2.30$ radians. In this case, we presently have no closed form expression for the frequency dependent MMS of such an object. However, under the assumption that the scattering characteristics of an eccentric object will be substantially different for the major versus minor axes, we hypothesises MMS spectra shown in Fig. 4 and Fig. 5 as solid lines and examine the performance of our approach under these conditions.

In this case, we estimate the center of the object, minor and major axis moment spectra and two rotation angles. Further, we assume that the optimum β_1 and β_2 values for the major and minor axis are known. For $\beta_1 = 0.001$ and $\beta_2 = 1$, after performing 10 Monte Carlo simulations at 20 dB SNR, the sample mean of the estimated object center is $(0.5002, 0.4995, 0.0969)\text{m}$ with a standard deviation of $\pm(0.0020, 0.0014, 0.0034)\text{m}$. The sample mean of estimated rotation angles are $\phi = 0.7439$ radians and $\psi = 2.3527$ radians with standard deviations of $\pm(0.0424)$ and $\pm(0.1271)$, respectively. The real and imaginary parts of the two estimated moment spectra for the major and minor axes are shown in Fig. 4 and Fig. 5, respectively.

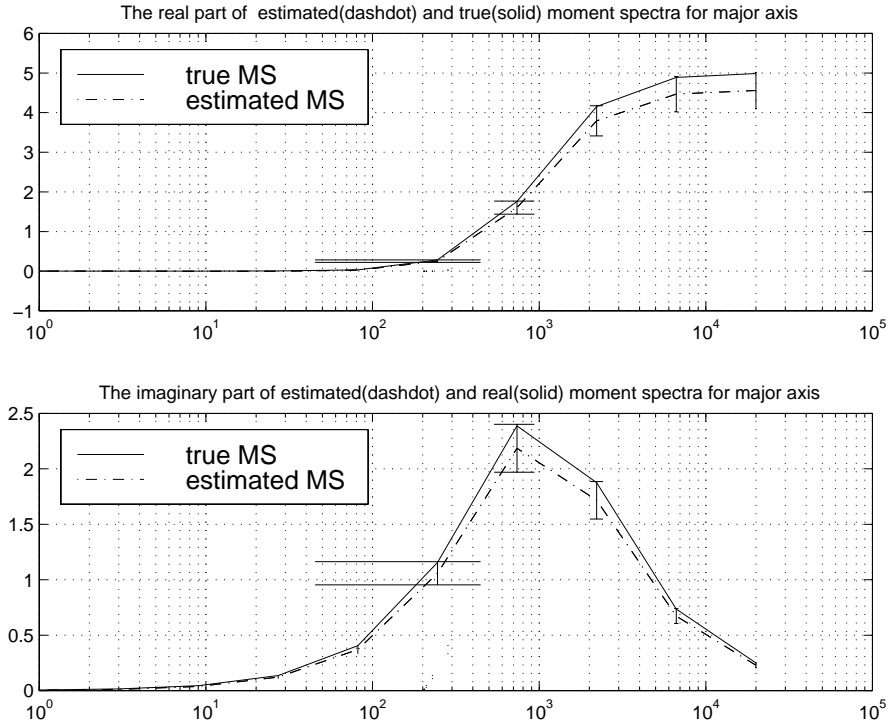

Figure 4. The real and imaginary part of estimated and real moment spectra of spheroid mine for $\beta_1 = 0.001$ and $\beta_2 = 0.001$, and for the major axis.

As a last example, we consider an ellipsoid object at the same location as the previous example. For this case we use the same data as for the second, spheroidal example; however, we lift the assumption that we know we are looking for a spheroidal object and instead estimate three MMS and three rotation angles. For $\beta_1 = 0.001$, $\beta_2 = 0.001$ and $\beta_3 = 1$, after we perform 10 Monte Carlo simulations at 20 SNR, the sample mean of the estimated object center is $(0.5003, 0.4992, 0.0911)\text{m}$ with a standard deviation of $\pm(0.0013, 0.0015, 0.0046)\text{m}$. The sample mean of the estimated rotation angles are $\phi = 0.7443$ radians,

[†]Note that because the object is taken to be spheroidal, two of the three principle axes are identical so we only need estimate a pair of rotation angles and a pair of MMS.

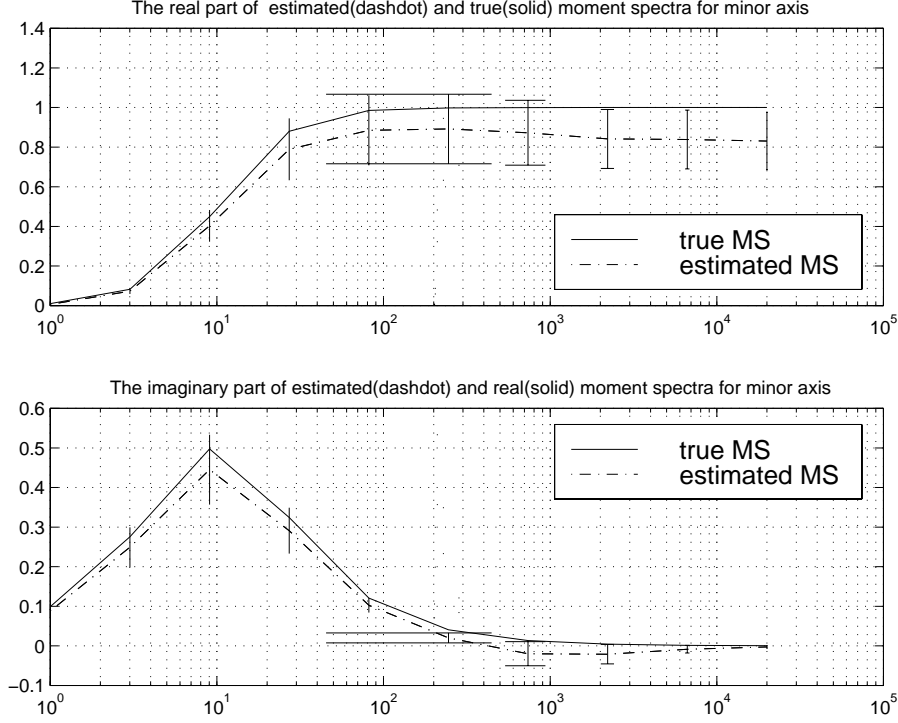

Figure 5. The real and imaginary part of estimated and real moment spectra of spheroid mine for $\beta_1 = 0.001$ and $\beta_2 = 1$, and for the minor axis.

$\psi = 2.5231$ and $\theta = 0.0619$ radians with standard deviations of $\pm(0.3015)$, $\pm(0.0841)$ and $\pm(0.2652)$ respectively. The real and imaginary parts of the estimated moment spectra for the three axes are shown in Fig. 6, Fig. 7 and Fig. 8, respectively. From Fig. 6 and Fig. 7 we see that the MMS estimates are approximately the same for the two equal axes. From this observation and the fact that the ϕ estimate was so close to zero, we conjecture that one could use these results in a classification scheme to conclude reliably that the object under investigation possessed spheroidal symmetry. Constructing such a classifier is a project we are currently pursuing.

The sample means of the estimated object center and rotation angles for three examples are illustrated in the following table with standard deviations. From all results the approach estimating the position, the rotation angle and the moment spectrum is highly precise.

	Sphere Case		Spheroid Case		Ellipsoid Case	
	mean	Standard Deviation	mean	Standard Deviation	mean	Standard Deviation
\hat{x}_0	0.5000	0.0003	0.5002	0.0020	0.5003	0.0013
\hat{y}_0	0.4998	0.0004	0.4995	0.0014	0.4992	0.0015
\hat{z}_0	0.0993	0.0030	0.0969	0.0036	0.0911	0.0046
$\hat{\phi}$	-	-	0.7439	0.0424	0.7563	0.3015
$\hat{\psi}$	-	-	2.3527	0.1271	2.5982	0.0841
$\hat{\theta}$	-	-	-	-	0.0619	0.2652

5. CONCLUSIONS AND FUTURE WORK

In this paper, we have presented a technique for the estimation of the MMS, the co-ordinates of the object center, and the rotation angles from EMIS data. Under this approach, the data are linearly related to the multipole moment spectra and non-linear functions of the object location and rotation angles. We determined the object center and rotation angles by using a low-dimensional non-linear optimization method and employed a linear least square inversion procedure to determine the estimates of the MMS.

While the results in this paper are encouraging much work remains to be done in this area. First, we are currently looking to verify our work by applying these methods to real sensor data in collaboration with Geophex Inc. Second, the closed form analytical nature of the model makes it well suited to extensive performance analysis based on Cramer-Rao lower bounds on the variances of the estimates we obtain for angles, location, and MMS. Using this performance metric allows one to start looking at issues of optimizing sensor configurations for particular detection/characterization problems. Moreover, for much of this work we assumed that we knew whether the targets of interest possessed spherical or ellipsoidal symmetry. More interesting is the case where we estimate three rotation angles and three moment spectra and employ a statistical test to determine the symmetry characteristics of the underlying target. Again, performance analysis is also of interest. Finally, as has been mentioned previously in this paper, from a modeling perspective we are currently looking to techniques for mapping object characteristics (size, shape, and material parameters) into the λ functions used in this model. As any such mapping represents an approximation to the true physics, it would be interesting to explore methods for doing this which explicitly minimize the error in the approximation.

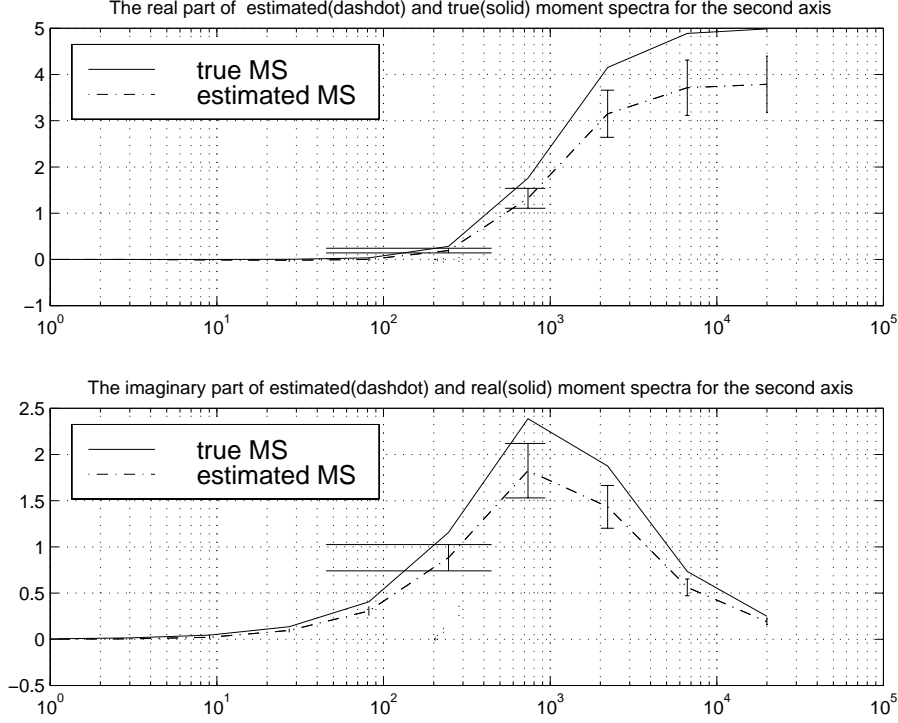

Figure 7. The real and imaginary part of estimated and real moment spectra of spheroid mine for $\beta_1 = 0.001$, $\beta_2 = 0.001$ and $\beta_3 = 1$, and for the second axis.

Abstract

We present an efficient, stable, recursive T-matrix algorithm to calculate the scattered field from a heterogeneous collection of spatially separated objects. The algorithm is based on the use of higher order multipole expansions that are typically employed in recursive T-matrix techniques. The use of these expansions introduces instability in the recursions developed in [1, 3] specifically in the case of near field computations. By modifying the original recursive algorithm to avoid these instabilities we arrive at a flexible and efficient forward solver appropriate for a variety of scattering calculations. The algorithm can be applied when the objects are dielectric, metallic, or a mixture of both. We verify this method for cases where the scatterers are electrically small (fraction of λ) or relatively large ($1-2 \lambda$). While developed for near field calculation, this approach is applicable for far field problems as well. Finally, we demonstrate that the computational complexity of this approach compares favorably with comparable recursive algorithms.

1 Introduction

Calculation of scattered electromagnetic fields is of interest in many different science areas. For example, an important component of many ground penetrating radar (GPR) problems is the efficient computation of the scattered fields produced by a collection of buried objects when illuminated by a radar source. The choice of technique for computing these fields is often driven by a variety of factors including computational complexity and the flexibility to handle easily a wide range of configurations of scatterers. In applications such as mine detection and hazardous waste removal objects can be either dielectric, metallic or mixtures. Their sizes can range from sub-wavelength to a few multiples of a wavelength. Therefore, one desires an efficient, flexible forward solver that is useful both for analysis and that can be incorporated into signal processing algorithms.

The most popular forward solver for these and related complex scattering problems, the Method of Moments (MoM) [6], is based on a fine discretization of the region of interest and requires the inversion of a large dense matrix to calculate the scattered field. As this task requires $O(N^3)$ calculations where N is the number of grid points, MoM is known to be quite computationally intensive. While fast multipole techniques [9] are useful for reducing the complexity of MoM-type linear systems, these algorithms are typically used for metallic objects and have theoretical difficulties with the spurious modes that can be circumvented only by “complexification” [12]. Finite difference techniques are also frequently used as forward solvers and like MoM rely on a full space discretization. Although the resulting matrices are sparse, one still faces the delicate task of specifying an absorbing boundary condition to terminate the computational grid.

Here we consider the use of transition matrix (T-matrix) methods [14,15] for solving the scattering problems of interest. Unlike MoM and finite differences, the T-matrix approach does not require an absorbing boundary condition and substitutes the discretization of space with harmonic

expansions of the fields thereby reducing the number of unknowns for a wide range of problems. For scattering problems involving single objects, this technique is applicable for metallic and dielectric scatterers. For problems involving multiple objects, Chew and co-workers have pioneered the development of a number of fast, recursive T-matrix algorithms for determining the scattered fields in a variety of scenarios [1–4, 8, 13]. For example, in [3], problems involving electrically large dielectric objects are considered. By tessellating the objects into many small sub-scatterers and using low order multipole expansions of the fields for each sub-scatterer the authors arrive at a highly efficient, T-matrix based algorithm for computing the scattered fields. In [4], Chew et.al. consider a scattering problem involving a group of metallic strips. Here the method of moments is used to compute the T-matrices for each, individual strip and the same recursion as in [13] is employed to solve the overall, multi-object scattering problem.

The motivation for the algorithm developed in this paper is the need to solve scattering problems for the GPR-type geometry shown in Fig. 1. Specifically, we are interested in the development and verification of a recursive algorithm capable of computing scattered fields from multiple dielectric and/or metallic objects in the near field. For simplicity, we considered an E_z polarized planewave incident on a two dimensional problem geometry in which multiple scatterers each possessing a circular cross-section (i.e. infinite circular cylinders) are located in an infinite medium of constant, complex permittivity. Because the use of a tessellated scheme is inappropriate for metallic objects, to handle this mixed-object problem we formulate a recursive algorithm based on high order harmonic expansions for the full scatterers. We demonstrate that this approach causes instabilities in the original recursive algorithm when near field computations are required. By modifying these recursions we obtain a stable algorithm which avoids these instabilities and which is capable of accurate near and far field calculations for the mixed scatterer problem of interest. Finally, we

demonstrate that this approach retains the low computational complexity of the method in [3].

The remainder of this paper is organized as follows. In Section 2 we review the T-matrix theory for single scatterers and the recursive T-matrix algorithm for multiple scatterers. In Section 3, we discuss how T-matrix techniques can be applied to GPR geometries, and we will present two alternative approaches to calculate the scattered field and the modification in the recursive algorithm. In Section 4, we will discuss the results and show examples and finally in Section 5 we will draw conclusions and suggest future work.

2 T-Matrix Background

2.1 Single Scatterer T-matrix

The total scalar electromagnetic (or acoustic) wave in a homogeneous background with a homogeneous scatterer is given by¹:

$$\psi(\underline{r}) = \psi^{inc}(\underline{r}) + \psi^{sca}(\underline{r}) \quad (1)$$

where $\psi^{inc}(\underline{r})$ is the wavefield incident on the scatterer and $\psi^{sca}(\underline{r})$ is the field scattered from the object.

Applying the Poincaré-Huygens principle and the Gauss theorem we can write the total field outside the scatterer as [11]:

$$\psi(\underline{r}) = \psi^{inc}(\underline{r}) + \int_S dS' \{ \psi_+(\underline{r}') \nabla' g(k|\underline{r} - \underline{r}'|) - [\nabla'_\perp \psi(\underline{r}')] g(k|\underline{r} - \underline{r}'|) \} \quad (2)$$

where S is a piecewise smooth surface enclosing the scatterer, ψ_+ and $\nabla'_\perp \psi$ are the total field $\psi(\underline{r})$ and its gradient on the outer surface of the scatterer, and $g(k|\underline{r} - \underline{r}'|)$ is the free space Green's function. The vectors \underline{r} and \underline{r}' are from the scattering origin to observation points and to source points on the scatterers, respectively. The Green's function can be expanded in terms of cylindrical

¹Time factor of $e^{j\omega t}$ is suppressed

basis functions (in 2-D) as follows [11]:

$$g(k|\underline{r} - \underline{r}'|) = -j\frac{\pi}{2} \sum_n \psi_n(k\underline{r}_{>}) Rg\psi_n(k\underline{r}_{<}) \quad (3)$$

where $\psi_n(k\underline{r}) = H_n^{(2)}(kr)e^{-jn\phi}$ are the basis functions representing traveling waves and $Rg\psi_n(k\underline{r}) = J_n(kr)e^{-jn\phi}$ are the basis functions representing the standing waves. Here, Rg stands for “regular part of”, $H_n^{(2)}(z)$ is the n th order Hankel function of second kind, $J_n(z)$ is the n th order Bessel function, and $\underline{r}_{>}$ ($\underline{r}_{<}$) means the larger (smaller) of \underline{r} and \underline{r}' .

Based on the same decomposition, the scattered and incident fields can be expanded as [11]:

$$\psi^{sca}(\underline{r}) = \sum_n f_n \psi_n(\underline{r}) = \underline{\psi}^T \underline{f} \quad \text{if } |\underline{r}| > |\underline{r}'| \quad (4)$$

and

$$\psi^{inc}(\underline{r}) = \sum_n a_n Rg\psi_n(\underline{r}) = Rg\underline{\psi}^T \underline{a} \quad (5)$$

where $\underline{\psi}$ and $Rg\underline{\psi}$ are column vectors filled with $\psi_n(\underline{r})$ and $Rg\psi_n(\underline{r})$, respectively and T stands for transposition.

The T-matrix now is defined as [11,14]:

$$\underline{f} = \mathbf{T}\underline{a}. \quad (6)$$

The elements of \mathbf{T} can be found by using (2), (3) and the boundary conditions. For a detailed analysis of the single object T-matrix method, the reader is referred to [14,15,11].

2.2 Recursive T-matrix Algorithm

The recursive T-matrix algorithm uses the basic principle of single scatterer T-matrix formulas in that for each object, the scattered fields from others are assumed a part of total incident field. This way for every scatterer a T-matrix can be assigned. The recursion starts with the T-matrices of individual scatterers, then one by one scatterers are incorporated into the equation and the T-matrices are updated until, for every scatterer, the final form of the T-matrix, including all multiple scattering effects, is obtained.

Formally, for L scatterers, the harmonic expansion of scattered field, similar to (4), can be written as [3]:

$$\psi^{sca}(\underline{r}) = \sum_{i=1}^L \underline{\psi}^T(\underline{r}_i) \mathbf{T}_{i(L)} \boldsymbol{\beta}_{i,0} \underline{a} \quad (7)$$

where $\mathbf{T}_{i(L)}$ is the T-matrix for i th object in the presence of L scatterers and $\boldsymbol{\beta}_{i,0}$ is the translation matrix used to translate same type basis functions between scattering coordinate center (x_s, y_s) and i th object's local coordinate center (x_i, y_i) , i.e. *standing* waves in i th local coordinate system to *standing* waves in 0th (scattering) coordinate system; or *traveling* waves in i th local coordinate system to *traveling* waves in 0th (scattering) coordinate system.² Fig. 1 pictorially shows the coordinate systems and how the translation matrices work. Expansion of the scattered field in (7) is valid if all observation points are outside the circle enclosing all scatterers. Following Chew's derivation, the recursive construction of $\mathbf{T}_{i(L)}$ can be written as [3, eq.10-11] :

$$\mathbf{T}_{n+1(n+1)} \boldsymbol{\beta}_{n+1,0} = \left[\mathbf{I} - \mathbf{T}_{n+1(1)} \sum_{i=1}^n \boldsymbol{\alpha}_{n+1,i} \mathbf{T}_{i(n)} \boldsymbol{\beta}_{i,0} \boldsymbol{\alpha}_{0,n+1} \right]^{-1} \mathbf{T}_{n+1(1)} \left[\boldsymbol{\beta}_{n+1,0} + \sum_{i=1}^n \boldsymbol{\alpha}_{n+1,i} \mathbf{T}_{i(n)} \boldsymbol{\beta}_{i,0} \right] \quad (8)$$

and

$$\mathbf{T}_{i(n+1)} \boldsymbol{\beta}_{i,0} = \mathbf{T}_{i(n)} \boldsymbol{\beta}_{i,0} + \mathbf{T}_{i(n)} \boldsymbol{\beta}_{i,0} \boldsymbol{\alpha}_{0,n+1} \mathbf{T}_{n+1(n+1)} \boldsymbol{\beta}_{n+1,0} \quad (9)$$

where $n = 1, 2, \dots, L, i = 1, 2, \dots, n$ and $\boldsymbol{\alpha}_{n,i}$ is the translation matrix used to change different basis functions between reference coordinate systems (Fig. 1), i.e. *standing* waves in n th local coordinate system to *traveling* waves in i th local coordinate system. The recursion starts with the individual T-matrices, $\mathbf{T}_{i(1)}$, of the scatterers, i.e. the T-matrix of the i th scatterer when there are no other scatterers in the medium.

Theoretically the matrices $\boldsymbol{\alpha}, \boldsymbol{\beta}, \mathbf{T}$ are of infinite dimension. T-matrix algorithms truncate these matrices with finite values N and M such that the residual error is below the machine precision

²The translation matrices $\boldsymbol{\beta}_{i,0}$ contain Bessel functions and complex exponentials. For details about these matrices see [1, 11].

or acceptable levels. Here N represents the number of harmonics used to expand the fields at the scattering origin and M represents the number of harmonics used to expand the fields in the objects' local coordinate systems. Thus, the T-matrix is of size $M \times M$, $\beta_{i,0}$ is of size $M \times N$ and $\alpha_{i,n+1}$ is of size $M \times M$. The parameters N and M are related to the distance of scatterers from the scattering origin and the radii of the scatterers, respectively. As the distances between scatterers and the scattering origin increase, N needs to be increased, and as the radii of scatterers increase, M needs to be increased [3].

3 A Modified Recursive T-Matrix Method

The work in this paper was motivated by the desire to obtain a fast, accurate forward modeling code for ground penetrating radar type geometries illustrated in Fig. 2. As discussed in Section 1 this application requires the computation of near field values of scattered field arising from mixtures of dielectric and metallic objects. To effectively handle these requirements, we propose a formulation of the recursive T-matrix algorithm based on the representation of the scattered field from each full object using high order expansions (i.e. large M) in the recursions in (8) and (9).

In principle, this approach supports the computation of scattered fields from arbitrary collections of dielectric and metallic objects. In fact, we demonstrate that this is true specifically for far-field calculations. Unfortunately, the use of higher order expansions results in an instability in a particular harmonic expansion formula upon which the original recursive T-matrix algorithm is based when near field computations are required. In the remainder of this section, we describe explicitly this difficulty and propose a modified recursion which by-passes this addition formula and results in a stable method for solving the problem of interest.

3.1 Determination of Scattering Origin

Unlike most radar applications, in a GPR measurement geometry the scattered field is generally observed in the near or intermediate field. Since the harmonic expansions upon which the recursive T-matrix algorithm is based have validity regions (see eqn.(4)), there are certain limitations as to where the scattering origin can be placed relative to the receiver array. In this section, we will briefly discuss how the scattering origin is determined, when the object locations and radii are given for the GPR-type configuration in Fig. 2. The triplet $(x_i, y_i; a_i)$ represents x and y coordinates and radius of the i th object relative to the global origin O_g and L is the number of objects buried under the receiver array.

Because of the requirements on the loci of observation points imposed by (4) for single objects and (7) for multiple objects, the scattering origin (x_s, y_s) relative to O_g must be selected such that there must be at least one circle, centered at (x_s, y_s) , encircling all objects with no receivers inside it. The dashed circle in Fig. 2 depicts such a circle. Assuming a linear receiver array, the condition to choose the scattering coordinate system is:

$$R_c < |y_s| \quad (10)$$

where

$$R_c = \max_{i \in \{1, 2, \dots, L\}} \left\{ \sqrt{(x_s - x_i)^2 + (y_s - y_i)^2} + a_i \right\}. \quad (11)$$

This condition must be met by individual objects as well as by all objects collectively. Therefore, we can rewrite the condition in (10) and (11) as the intersection of regions as follows:

$$(x_s, y_s) \in \left\{ (x, y) \mid \bigcap_{i=1}^L \sqrt{(x - x_i)^2 + (y - y_i)^2} < |y| - a_i \right\}. \quad (12)$$

In fact, each term under the intersection sign in (12) defines the region under an upside-down parabola. Fig. 3 depicts the parabolic regions for three objects. Placement of objects in this figure is very typical of a mine detection problem. In this geometry, any point inside the shaded

area, representing the intersection of all three parabolic regions, can be selected as the scattering origin. Ideally, we can place the scattering origin at $y_s \approx -\infty$. This choice of (x_s, y_s) will always satisfy the condition in (10). However, the order of harmonics used in the T-matrix algorithm is proportional to the distance between scattering origin and object centers [3], i.e. $N \propto kr_i$ where N is the harmonic used for translations to and from the scattering origin, k is the wave number and $i = 1, 2, \dots, L$. Therefore, the optimum scattering origin should be within this shaded area and as close as possible to the objects in order to minimize the harmonics used for translations. As we show in Section 3.2, with this choice of (x_s, y_s) , the distances between object centers and the scattering origin can be very close, which causes convergence problems in the addition formulas of T-matrix algorithm. In Section 3.3, we describe a modification in the recursive T-matrix algorithm that lets us use the algorithm with optimum choice of scattering origin.

3.2 Problems With Higher Order Harmonic Expansions

The convergence problems alluded to earlier can be traced to the fact that equation (8) uses the identity

$$\alpha_{p,q} = \beta_{p,0} \alpha_{0,q} \quad \text{if } |\underline{r}_q| \geq |\underline{r}_p| \quad (13)$$

which in turn requires the ordering of the objects such that $|\underline{r}_1| \leq |\underline{r}_2| \leq \dots \leq |\underline{r}_L|$. By using definitions of $\alpha_{p,q}$, $\beta_{p,0}$ and $\alpha_{0,q}$ [1,11], we can write the (m, m') th entry, $[\alpha_{p,q}]_{m,m'}$, as:

$$H_{m-m'}^{(2)}(k|\underline{r}_{pq}|)e^{-j(m-m')\phi_{pq}} = \lim_{N \rightarrow \infty} \sum_{n=-N}^N J_{m-n}(k|\underline{r}_p|)e^{-j(m-n)(\phi_p+\pi)} H_{n-m'}^{(2)}(k|\underline{r}_q|)e^{-j(n-m')\phi_q} \quad (14)$$

where $\underline{r}_{pq} = |\underline{r}_{pq}|e^{-j\phi_{pq}} = \underline{r}_q - \underline{r}_p$ and $\underline{r}_i = |\underline{r}_i|e^{-j\phi_i}$, $i = p, q$. This truncated sum does not converge if $\underline{r}_q = \underline{r}_p + \underline{\delta}$ where $|\underline{\delta}|$ is small as compared to $|\underline{r}_p|$ and $|\underline{r}_q|$, and if $m - m'$ is a large number ($-M \leq m \leq M$ and $-M \leq m' \leq M$.) Fig. 4 shows the convergence of the series in (14) for the corner entries of (13) for $M = 5$, i.e. $\max\{m - m' = 10\}$. Here we have three curves, showing the

convergence for $\underline{\delta} = 0.1r_p$, $\underline{\delta} = 0.25r_p$ and $\underline{\delta} = 0.5r_p$, $M \geq 5$ and $\underline{\delta} < 0.1r_p$ are typical parameter choices for the problems of interest in this paper. It is clear from this figure that as the magnitudes of two vectors get closer, the convergence rate slows. Chew et.al. [4] suggested a windowed addition theorem (which is originally developed for H_z polarized scattering) to overcome this problem, but the implementation of this method introduces two new variables to choose in order to set the width and shape of the window. In addition, the implementation of windowed summation introduces errors in the sum for vectors for which the convergence is not a problem.

It should be noted that not all valid scattering origins for a given problem give rise to this convergence problem. Indeed, trial an error will quickly demonstrate that, for a given collection of scatterers, there exist scattering origins where the original T-matrix recursions work just fine. These points are typically far from the scatterers thereby requiring large N in the recursions and moreover there does not appear to be an easy means of *a priori* determining whether a chosen origin will or will not give rise to a coverage difficulty. Thus, in the following sections, we introduce a modified recursion which bypasses the convergence issue for all valid scattering origins thereby allowing us to use the closest valid origin (i.e. smallest N) to solve the problem.

3.3 Modified Recursive T-Matrix Algorithm

The recursion in (8) and (9) takes place over the quantities $\mathbf{T}_{i(n)}\boldsymbol{\beta}_{i,0}$, and we have determined that the convergence problem stems from (13). Therefore, to eliminate the need to use this identity, we go one step back in the derivation of recursion formulas, and write (8) as [3, eq.7-8]:

$$\mathbf{T}_{n+1(n+1)}\boldsymbol{\beta}_{n+1,0} = \left[\mathbf{I} - \mathbf{T}_{n+1(1)} \sum_{i=1}^n \boldsymbol{\alpha}_{n+1,i} \mathbf{T}_{i(n)} \boldsymbol{\alpha}_{i,n+1} \right]^{-1} \mathbf{T}_{n+1(1)} \left[\boldsymbol{\beta}_{n+1,0} + \sum_{i=1}^n \boldsymbol{\alpha}_{n+1,i} \mathbf{T}_{i(n)} \boldsymbol{\beta}_{i,0} \right] \quad (15)$$

and (9) as:

$$\mathbf{T}_{i(n+1)}\boldsymbol{\beta}_{i,0} = \mathbf{T}_{i(n)} \left[\boldsymbol{\beta}_{i,0} + \boldsymbol{\alpha}_{i,n+1} \mathbf{T}_{n+1(n+1)} \boldsymbol{\beta}_{n+1,0} \right] \quad (16)$$

without using (13). Since (13) is not used in (15) and (16) we can base a new recursion on these two equations and the identity:

$$\beta_{i,0}\beta_{0,i} = \mathbf{I} \quad (17)$$

where $\beta_{i,0}$ is $M \times N$, $\beta_{0,i}$ is $N \times M$, and (17) holds as long as $N > M$ which is always true as long as objects are not overlapping. By using (15), (16) and (17) the modified recursion equations can be written as:

$$\mathbf{T}_{n+1(n+1)}\beta_{n+1,0} = \left[\mathbf{I} - \mathbf{T}_{n+1(1)} \sum_{i=1}^n \alpha_{n+1,i} \mathbf{T}_{i(n)} \beta_{i,0} \beta_{0,i} \alpha_{i,n+1} \right]^{-1} \mathbf{T}_{n+1(1)} \left[\beta_{n+1,0} + \sum_{i=1}^n \alpha_{n+1,i} \mathbf{T}_{i(n)} \beta_{i,0} \right] \quad (18)$$

and

$$\mathbf{T}_{i(n+1)}\beta_{i,0} = \mathbf{T}_{i(n)}\beta_{i,0} + \mathbf{T}_{i(n)}\beta_{i,0}\beta_{0,i}\alpha_{i,n+1}\mathbf{T}_{n+1(n+1)}\beta_{n+1,0}. \quad (19)$$

Note that the recursion is still over the same block, $\mathbf{T}_{i(n)}\beta_{i,0}$, but since (13) is eliminated these new recursion equations do not suffer from convergence problems.

As reported in [3] the original recursive T-matrix algorithm has a complexity of $O(M^2N)$ per recursion. It is easily shown that the modified algorithm also has a complexity of $O(M^2N)$ per recursion with a slightly larger constant in front of M^2N resulting from extra multiplications to obtain $\mathbf{T}_{i(n)}$ from $\mathbf{T}_{i(n)}\beta_{i,0}$. To calculate the scattered field from L objects, $L(L-1)/2$ recursions are required. Therefore, the overall complexity of both the recursive and modified recursive algorithm is $O(L^2M^2N)$.

4 Discussion And Examples

In this section, we first verify our new scattering algorithm against published results and then provide a collection of examples that are particularly relevant for near field, GPR-type applications. As most previously published results for mixed scatterer problems involve far field computations, in verifying our approach we also demonstrate its ability to handle far zone calculations. Where

appropriate, we compare the computational complexity of our higher order, modified recursive algorithm (HO-MRA) against two alternate T-matrix approaches. First, we implement the lower order, original recursive algorithm (LO-ORA) of [3] for near and far field, dielectric-only problems. For far zone problems with mixtures of dielectric and metallic scatterers, we consider high order (i.e. large M) forms of the original recursions (labeled HO-ORA here) (8) and (9), where, because of the far field assumption, the instability problem is not an issue.

Before we proceed, we define the terms used in this section. The echo width, i.e. scattering cross-section per unit length, and normalized echo width are defined as [10]:

$$\sigma(\phi) = \lim_{r \rightarrow \infty} 2\pi r \left| \frac{\psi^{sca}(\underline{r})}{\psi^{inc}(\underline{r})} \right|^2, \quad (20)$$

and

$$\sigma_n(\phi) = \sqrt{\frac{\sigma(\phi)}{\lambda}} \quad (21)$$

where λ is the wavelength in the medium of propagation. The normalized scattering field pattern is defined as:

$$F(\phi) = 10 \log_{10} \left\{ \lim_{r \rightarrow \infty} 2\pi r \frac{|\psi^{sca}(\underline{r})|^2}{\max\{|\psi^{sca}(\underline{r})|^2\}} \right\}. \quad (22)$$

In order to ensure that the modified algorithm can indeed find the true scattered fields, we verified our calculations against published scattered field patterns. We first calculated the scattered field due to two dielectric cylinders placed in free space, each with relative dielectric constant of 2.6, and radius of 0.5λ . The distance between the cylinders is 3λ (Fig. 5(a).) An E_z polarized planewave is incident from 0° . Fig. 5(b) shows the echo width calculated using the HO-MRA of this paper (solid line), the LO-ORA of [3] (dashed line) and results in [10] (circles). Fig. 6(b) shows a similar comparison for a mixed object case depicted in Fig. 6(a), i.e. one cylinder is metallic and the other is lossy dielectric with $\epsilon_r = 4 - j5$. For this case, we did not include the echo width calculated using the original recursive algorithm, since the method in [3] is limited to dielectric

objects. As in previous examples, the echo width obtained using the modified algorithm and that reported in [10] are very close.

Next, we compared the scattering patterns for two metallic cylinders. In this case both cylinders have a radius of 1.1λ ($ka = 7$) and separated by a distance of 2.6λ ($kd = 16$.) Fig. 7(a) shows the scattering geometry for this example and (b) shows the scattered field patterns of both our solution (solid line) and the one given in [5] (circles.) As seen from these figures, the scattering pattern obtained using the modified algorithm and that given in [5] are very close.

Now, we present scattering examples that are especially useful in GPR applications. All objects are assumed to be buried in a homogeneous, lossy background ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} S/m$; typical properties of 5% moist San Antonio clay loam or 10% moist Puerto Rico clay loam [7]); the operating frequency is $1GHz$ and a planewave is incident from 90° , see Fig. 8(a). We first find the scattered field from 3 dielectric mine-like objects with diameters $7.5cm$ as shown in Fig. 8(a). All objects have a relative permittivity of 2.5. The scattering origin has to be placed far away from the receiver array ($x_s = 0.5m$, $y_s = -1.25m$), because the objects are close to the receivers, which in turn requires a large value, 120, for N . For this case, we calculated the scattered field using both the LO-ORA and HO-MRA defined in Section 2.2 and Section 3.3, respectively. Fig. 8(b) shows the scattered fields observed along the receiver array using the HO-MRA (solid line) and the LO-ORA (circles). It is clear from this figure that both approaches yield very similar fields but the computational complexity (flop count) of our method is 18.94×10^6 flops while that of the tessellated scheme is 1671×10^6 flops.

The second GPR example depicts a mixed mine-like object case since the objects at the sides are metallic and the object at the center is dielectric with a relative dielectric constant of 2.5, Fig. 9(a). The mine-like geometry is unchanged and the scattering origin is still at ($x_s = 0.5m$, $y_s = -1.25m$).

As a result $N = 120$, and since the object radii are relatively small $M = 12$. The scattered field observed along the receiver array for mixed mine-like object case is shown in Fig.9(b). The last example demonstrates the calculation of scattered field from buried waste drums. For this case we have 2 metallic drums of radius $0.3m$ buried in the same lossy background before, as shown in Fig. 10(a). The scattering origin is placed at $(x_s = 1m, y_s = -1.37m)$ to minimize the harmonics used in the expansions ($M = 25, N = 110$). For drum case M is quite large since the radii of the objects are considerably large. Fig. 10(b) shows the scattered field observed along the receiver array placed directly above the cylinders.

Having verified the scattering field patterns of new recursion with the ones in the literature and presented the GPR examples, we compared the complexities of the HO-MRA, LO-ORA, and HO-ORA. To ensure a fair comparison, whenever a tessellation is required, we set the density of sub-scatterers to be close to that used in [3]. Performance of the each approach is measured by the floating point operations (flops) required to calculate the scattered field. Table 1 shows the flop count of all three recursive T-matrix algorithms that can be used to find the scattered fields from multiple, spatially separated cylinders. Table 2 shows the number of scatterers L , harmonics M , N and the location of the scattering origin (x_s, y_s) used in these examples.

The first three rows of Tables 1 and 2 correspond to examples from the two dimensional scattering literature. For these cases, all observation points are in the far field so that the convergence problem alluded to earlier is not an issue. As a result, with dielectric objects HO-MRA, LO-ORA and HO-ORA can be used to calculate the scattered field. LO-ORA is used only with dielectric objects [3] and as seen from Table 1 its computational complexity is quite large as compared to HO-MRA and HO-ORA. The reason behind this large complexity is that numerous sub-scatterers are required for each cylinder. The computational complexity of HO-ORA is at most 15% less than that of

HO-MRA since the latter needs extra multiplications to obtain $\mathbf{T}_{i(n)}$ from $\mathbf{T}_{i(n)}\boldsymbol{\beta}_{i,0}$.

The last three rows of Table 1 show the flops needed to find the scattered field for GPR-specific examples and Table 2 shows the number of scatterers, harmonics and the locus of the scattering origin used in these examples. The geometries of GPR cases of interest are depicted in Figures 8(a), 9(a) and 10(a). Unlike previous examples, GPR problems require measuring the scattered field in the near field, which restricts the regions where the scattering origin can be placed. As we have shown in Section 3, the choice of optimum scattering origin results in convergence problems in HO-ORA, making it inaccessible for GPR geometries. In addition LO-ORA is not used with metallic objects leaving only HO-MRA for all GPR geometries and all material types. Even when LO-ORA is used for dielectric-only objects, one has to spend approx. 88 times more flops than it is needed for HO-MRA (Table 1).

5 Conclusions

In this paper, we present a new recursive T-matrix algorithm specifically designed for the efficient solution of near field scattering problems involving heterogeneous collections of metallic and dielectric objects. We have verified this algorithm against previously published results thereby demonstrating its utility for far field computations and indicated its use for GPR-type scattering problems. For near and far-field dielectric scattering problems, this algorithm is significantly more efficient than the sub-scatterer method in [3]. For far-field computations, the technique in this paper is slightly more costly than the use of higher order expansions in the original recursive formulae.

The work in this paper suggests a variety of additional research directions. First, we are quite interested in extending the modified recursive algorithm into three dimensions while simultaneously considering scattering problems involving irregularly shaped objects where the T-matrices would be

computed using the method of moments as in [4]. Such work would allow for the easy examination as to how object shape and orientation impacts the scattered fields and ultimately, the ability to detect and localize objects. In terms of the GPR application which originally motivated this effort, we are looking to T-matrix type methods which might allow for some level of modeling the air-earth interface relevant in these scenarios without destroying the computational efficiency of the scattering model. Finally, applying the near field computational abilities of this approach to other application areas would be quite interesting.

Abstract -- The three-dimensional, wideband, bistatic ground penetrating radar (GPR) scatter response of rough, realistic ground is efficiently and accurately simulated using a hybrid high resolution 3-D and large area 2-D FDTD model. The 3-D computation carefully models the transmitting and receiving antennas, while the 2-D FDTD models wave propagation between the antennas and the scattering by the soil below them. The FDTD soil model considers realistic frequency dependent (dispersive) soil with Gaussian height variations. The modeling results are compared to experiments performed with the Geo-Centers, Inc. commercially available GPR system used for mine detection. Despite the simplicity of the 2-D model, the results of the simulation and the experiment agree quite well.

Introduction

Ground penetrating radar is widely used to detect buried objects including land mines and buried waste containers, in excavation planning, and in roadway and bridge structural quality assessment [1]. Computationally modeling the performance of GPR is important in determining its feasibility in various situations and for designing the best sensing system for the given application. Appropriate computational models, such as the finite difference time domain (FDTD) method [2, 3], can be used for transmitter/receiver design and in parameter studies that include soil moisture and density variations [4]. The FDTD method is particularly well suited both for modeling soil surface roughness and volume inhomogeneities and the complex structures of wideband GPR antennas. Computational modeling is an essential complement to laboratory and field GPR experiments, which are particularly hard because of the difficulty in burying objects so they appear to be in long undisturbed ground.

The most accurate models for GPR are three dimensional, but 3-D FDTD modeling is computationally complex and expensive. Two-dimensional FDTD models can simulate much of the characteristic performance of GPR with orders of magnitude less computational expense. To model the entire link between the signal fed to the transmitting antenna and the signal measured at the output port of the receiving antenna, a reasonable compromise is to combine 3-D and 2-D models.

The present approach models the complex antenna volume with 3-D FDTD with a mesh fine enough to capture the variations in material geometry, and combines it with lower resolution free-space and soil scattering models using multiple 2-D FDTD meshes. As long as the small-scale wave variations (such as in the vicinity of the antenna or a localized three-dimensional scatterer) are partitioned in the 3-D model, the remaining piecewise-plane-wave-like propagation can be modelled with 2-D computation without introducing too much inaccuracy. Three-dimensional reflection from, and transmission through planar boundaries are also adequately approximated with 2-D FDTD, as long as the boundary is perpendicular to the computation plane. In addition, the distortion effects of random rough ground can be included in this 2-D modeling scheme. Although rough ground has randomness in two surface dimensions, as long as the surface height variation is small compared to the excitation wavelength, the depolarization and out-of-plane scattering effects are small. Fast computation is particularly important when the average scattering response of many surface realizations of random rough ground must be calculated.

In a subsequent study, the scattering of buried targets will be reported. In this present report, only the rough ground surface scattering with no target in the soil will be discussed. Indeed, to understand the scattering mechanisms of buried targets, it is first necessary to test the transmission through the ground surface and quantify scattering from the ground surface, which is the greatest source of clutter. We model the scatter response of realistic soil using the geometry and parameters employed by the Geo-Centers, Inc. Energy Focused Ground Penetrating Radar (EFGPR).

Geo-Centers EFGPR

The EFGPR is a time domain focused multistatic linear array radar used for buried mine detection. Each element of the array is a wideband transverse electromagnetic rhombus (TEMR) antenna, which resembles a bow-tie antenna that is rolled back and joined to itself using a pair of resistors. The measured performance of the TEMR indicates a very uniform radiation pattern in both planes throughout a broad frequency range [5]. This TEMR antenna is used for both transmitting and receiving elements. A Picosecond Labs, Inc. pulser feeds the elements with a single nanosecond pulse with the frequency response between 700 MHz and 1.3 GHz.

In order to enhance the performance of TEMR antennas in detecting buried mines, the transmitting and receiving antennas elements in the array (shown in Fig. 1) operate simultaneously in a fully multistatic radar mode. The system can also be used in studying the scattering response of the ground surface in order to understand the scattering mechanism of buried mines.

As shown in Fig. 1, the distance between the centers of adjacent transmitters, and between adjacent receivers, is about 0.244m, as is the distance between centers of transmitter T_i and corresponding receiver R_i ($i = 1,2,3,4$). The transmitter and receiver linear arrays lie about 0.39m above the ground surface. The transmitters and receivers are arranged in the x - z plane, with z -polarization so that waves incident in planes parallel to

the y - z plane are transverse magnetic (TM), while those incident in the x - y plane are transverse electric waves (TE).

The multistatic nature of the EFGPR array configuration allows for focusing on sample volumes of the subsurface and enhances the target signal to noise ratio. Examining a target from multiple views not only increases the response of the desired signal, but also reduces ground surface clutter, since different patches of ground are illuminated by the different sources and viewed by different receivers, and these variations tend to cancel. To characterize the ground clutter response for this array configuration, each possible transmitter element/receiver element combination must be analyzed separately. This is adequately modeled by considering the received signals at the four receivers R_1 , R_2 , R_3 and R_4 due to just transmitter T_1 . One aspect of these various links is that although the transmitting and receiving antenna elements are both z -polarized, the wave interactions with the ground have both TE and TM components.

FDTD Simulation

The link between the pulser input signal and received output voltage involves three modeling steps: one for the transmitting TEMR antenna, one for the receiving TEMR antenna, and one for the propagation through air and scattering from ground. The TEMR antennas have been successfully modelled with fine resolution ($\Delta = 0.00152\text{m}$) in three dimensions in both transmit and receive modes, as reported in Sahin [6]. The measured

transmitter excitation pulse is shown in Fig. 2. The waves radiated from the downward pointing transmitting antenna are first computed for all electric and magnetic field components throughout the 161 X 161 X 108 point grid, and the entire time record of electric field on the six bounding faces of the surrounding rectangular box are stored. Next, these calculated field values are coupled to a coarser 2-D grid by down-sampling by a factor of eight at grid points along the line segments where the transmission (2-D incidence) plane intersects the faces of the bounding box.

In addition, to avoid corner issues, the fields on the vertical (x - y and y - z) sides of the bounding box are projected onto the line crossing the bottom face (referred to as the aperture line), as shown in Figure 3. This aperture line will serve as one of the edges of the 2-D computational grid along which the excitation will be specified. It is tilted at an angle θ relative to the z -axis to account for the varying angle between transmitter and receiver. Since most of the transmitted power from the TEMR antenna propagates through the bottom face of the bounding box, the projected fields propagating through the side faces primarily ensures a smooth fall-off of power past the edge of the bottom box face. The projection of the fields from the side faces is accomplished by: 1) determining the approximate antenna phase center, 2) tracing rays from this center to the aperture line, 3) determining the attenuation spreading factor and time delay based on the length of this ray, 4) finding the electric field values at the point where the ray intersects the side face, and 5) converting these values to appropriate values on the aperture line.

The first step of finding the phase center uses the time domain fields on the bottom face of the bounding box. It is assumed that all outward propagating waves follow rays originating at the same point at the same time, as in the case of a pyramidal horn antenna [7]. By symmetry, the phase center lies along the centerline of the bounding box perpendicular to—and at a height y_c above—the aperture line. Two observation points along the aperture line are selected: one in the center, and one near the edge of the bounding box. The peak of the time pulse at each of these points is found, and its time and amplitude are recorded. Next, the distance y_c along the centerline is found by equating the path length difference between each of the two observation points and the phase center ($r_1 = y_c$ and $r_2 = \sqrt{y_c^2 + 11.6^2}$) to the time difference between the observed pulse peaks multiplied by the speed of light. The observed 210 ps time difference between arrival times of the peaks leads to $y_c = 7.5$ cm, or about 49Δ .

The second and third steps follow from similar triangles. Given the distance along the aperture line from the box centerline to the edge of the bottom face d , a point on the box side face y' projects out a distance $z' = d y_c / (y_c - y')$ along the aperture line (when $f = 0$). The distance from the phase center to this projected point is $r_p = \sqrt{y_c^2 + (d + z')^2}$, while the distance to the point on the ray at the box face is $r_f = \sqrt{(y_c - y')^2 + d^2}$. The relative time delay for the projected point relative to the point on the ray at the box face is $(r_p - r_f)/c$, and the relative attenuation is approximately r_f/r_p . A similar analysis holds for $f \neq 0$.

The fourth and fifth steps involve resolving the electric field components on the box edge face $\bar{E}(y', z = d)$ into tangential and normal components to the aperture line at the point where it intersects the projecting ray $\bar{E}_a = \hat{z}\bar{E} \bullet \hat{z} + \hat{y}\bar{E} \bullet \hat{y}$

The resulting fields \bar{E}_a are finally down-sampled in time by about a factor of seven, to yield a Courant Number of 0.5. These transverse and normal electric field components are then passed in an array of 247 time steps by 80 positions, as input to the 2-D FDTD soil scattering model along the top boundary. Fig. 4 shows one half of this array of E_{az} field values for the TE excitation. A similar array would be used for the other 2-D incidence planes.

One difficulty with dividing the model into separately calculated pieces is that the reverse coupling of waves scattered from the ground back into the transmitting antenna is ignored. This is only important from the receiver signal point of view if this backscattered wave then rescatters from the transmitting antenna. However, this effect is small, since all elements in the physical array are isolated with absorber to minimize both this rescattering and the direct-coupled signal from transmitter to receiver.

To use the 2-D FDTD to model the scattering response of the ground surface, we transform coordinates such that the incident plane includes the T_l/R_i ($i = 1,2,3,4$) antenna pair and is perpendicular to the ground. Designating the incidence plane as the X_i-Y_i plane as shown in Fig. 5, the 2-D FDTD now approximates the transmitter and receiver as infinitely long in the Z_i -direction. Since the ground surface is infinite and

perpendicular to the incidence plane, it is well modelled with 2-D FDTD. For the angle between the x -axis and X_i axis given by β_i , the electric field components in xyz coordinates, the correspond to field components in the $X_iY_iZ_i$ frame as:

$$E_{Xi} = E_x \cos \mathbf{b}_i + E_z \sin \mathbf{b}_i, \quad (1)$$

$$E_{Zi} = E_x \sin \mathbf{b}_i - E_z \cos \mathbf{b}_i, \quad (2)$$

$$E_{Yi} = -E_y. \quad (3)$$

Since the incident electric field is neither perpendicular nor parallel polarized to the incidence plane (X_i - Y_i plane) for some transmitter/receiver pairs, it is impossible to use the 2-D FDTD TE or TM codes directly. Instead, the perpendicular (E_{Xi} , E_{Yi}) and parallel (E_{Zi}) polarization components are first calculated by vector transform, then a TE FDTD code is used for the parallel polarized field while a TM code is used for the perpendicular field. The TE and TM components of the receiver field can be transformed similarly.

The space grid chosen for the 2-D FDTD air/ground interaction code is a 361×200 with space increment $\Delta = 0.0122$ m. The time increment $\Delta t = 20.5 \times 10^{-12}$ s, was chosen to maintain the Courant stability condition $c\Delta t / \Delta < 1/\sqrt{2}$. The distance between the centers of transmitter and receiver is 20 grid points (0.244m) and the bottom plane of the transmitter/receiver pair is 32 grid points, 0.39 meter above the ground surface. The soil is modelled as Puerto Rican clay loam with 5% moisture and 1.4 g/cm^3 density with dielectric constant and conductivity varying across the frequency band from 4.5 to 4.35 and 0.012 to 0.045 S/m respectively [8]. We model the frequency dependence of the soil

medium using the Z-transform representation of conductivity with constant dielectric constant [9], where $Z^{-1} = \exp(-j\omega \mathbf{D}t)$ is the Z-transform variable corresponding to a unit delay in the time domain:

$$\mathbf{s}(Z) = \frac{b_0 + b_1 \cdot Z^{-1} + b_2 \cdot Z^{-2}}{1 + a_0 \cdot Z^{-1}} \quad (4)$$

The parameters are chosen to match measured values of soil over the 30 MHz to 4 GHz frequency range: $b_0 = 0.5843$, $b_1 = -1.0649$, $b_2 = 0.4811$, $a_0 = 0.88$, and the average value of dielectric constant is $\epsilon_{Av} = 3.136$. With this conductivity model, a finite time difference equation relating conduction current to E-field is straightforward. The Perfect Matched Layer (PML) absorbing boundary condition for both free space and dispersive soil is used in the model [10]. Both flat and rough ground surfaces are used in our simulation. The roughness of the measured ground surface is accurately modeled with a Gaussian height distribution with zero mean and standard deviation σ_h , given by the probability density function relating two heights z_1 and z_2 separated by a distance x_d [11]:

$$p(z_1, z_2) = \frac{1}{2\sigma_h^2 \sqrt{1 - R^2(x_d)}} \exp\left(-\frac{z_1^2 - 2R(x_d)z_1z_2 + z_2^2}{2\sigma_h^2(1 - R^2(x_d))}\right) \quad (5a)$$

where the auto-correlation function of lateral distance is given by:

$$R(x_d) = \exp\left(-\frac{x_d^2}{l_c^2}\right) \quad (5b)$$

The standard deviation of surface height σ_h is about 1.8 cm and correlation length l_c is about 18 cm. Although with this height variation 95% of the excursion from flat is within ± 3.6 cm (or about $\pm 3\Delta$), the FDTD calculation shows noticeable differences compared to those for flat ground.

The results of the 2-D FDTD computations for waves radiated by T_I , which impinge on each of the four receivers, are shown in Fig. 6. Only one realization of rough ground is used for the responses displayed in this figure; other realizations yielded similar responses. For R_I , only the TE calculation is used, while for the three other receiver positions, the incident wave is divided into TE and TM components, each component is propagated separately, and then the waves impinging on each receiver is recombined. Note that eliminating roughness increases wave coherence, resulting in greater scattered amplitudes, but also leads to a slight delay relative to the rough ground calculation.

Antenna Transfer Function

The signal measured at each receiver output port in the experiment is an output voltage, while the signal obtained by the 2-D FDTD simulation is the electric field incident on the receiver location. Rather than perform another 3-D FDTD calculation on the receiving TEMR antenna, the receiving TEMR antenna transfer relation is used to convert the incident quasi-plane wave into the received voltage. The transfer function in the frequency domain can be obtained by dividing Discrete Fourier Transforms of the

receiver output voltage by that of its corresponding incident plane wave E-field [12]. The required receiver output voltage for the ground scattered case is thus obtained by Fourier transforming the field at the receiver, multiplying by the transfer function, and Inverse Fourier Transforming the result. In addition, before inverse transforming, we use a Wiener filter given by:

$$WF(k) = \frac{X^*(k)}{|X(k)|^2 + \epsilon} \quad (6)$$

where $X(k)$ is the DFT wave signal at the given receiver position, and $\epsilon = 10^{-5}$. The Wiener filter reduces the numerical noise in the TEMR antenna transfer function. The magnitude of the transfer function is shown in Fig. 7.

Results and Analysis

Fig. 8 shows the received voltages at the output terminals of R_1 , R_2 , R_3 , R_4 when T_1 is used as the transmitter, calculated by the hybrid 2-D/3-D FDTD model for both rough and flat ground and compares them to corresponding signals measured in the field. These signals are obtained by applying the antenna transfer function of Fig. 7 to the incident wave signals of Fig. 5. The experimental results were obtained at the Northeastern University Dedham test track. TEMR antenna elements were used as both transmitters and receivers in the configuration of Fig. 1 [13]. For each transmitter/receiver pair, the measured signals vary for different positions along track. To obtain a representative set of

measured responses, each sample signal from each position is shifted in time to align its first peak. Then the shifted sample signals for each of the four transmitter/receiver pairs are added and divided by the number of samples. These averages are taken to be the measured signals to be compared to calculated signals. This procedure takes account of the differences caused by ground surface variations along the track, but has the disadvantage that some of the small signal features are averaged-out.

To compare the amplitudes of the measured and calculated signals, each of the average measured signals are divided by the maximum average measured T1/R1 signal, and each of the calculated flat ground signals are divided by the maximum flat ground T1/R1 signal. The resulting maximum average measured signal values for T1/R2, T1/R3 and T1/R pairs are 0.9217, 0.4875 and 0.2490 respectively. The maximum calculated flat ground signal values for T1/R2, T1/R3 and T1/R pairs are 0.8145, 0.4621 and 0.2434 respectively. The close correspondence between measured and calculated maximum signal values indicate that the procedure for modeling source and receiver polarization variation is valid.

The main peaks of the FDTD calculated and measured signals have similar shape and width, and the leading behavior of each the signals is similar. The correspondence between the trailing (late time) behavior of the measured and calculated signals is worst for the closest transmitter/receiver pair (T1/R1), probably due to the multiple scattering from the ground back to the transmitter, which is ignored in the hybrid computational model. Although the largest negative excursion of the FDTD signals are slightly

different from those of the experiment, the results of the FDTD calculation are otherwise close to those of the experiment. The difference between the FDTD calculated voltage signals for rough ground and flat ground are smaller than those of the corresponding incident waves.

Considering the various approximations: 1) the actual 3-D propagation and scattering are modelled with 2-D calculations; 2) the ground surface is modelled as a rough curve in 2-D FDTD rather than a true rough surface with variations in two directions; 3) the ground scattered wave is modelled as a plane wave incident on the receiving antenna; 4) the approximations made when extrapolating the transmitted electric fields from the sides of the 3-D computational domain; 5) the possible inhomogeneity and uncertain soil type, moisture, and density inherent in the actual experiment; 6) the averaging of the experimental data for varying ground surface; and 7) the variations in the electronically generated wideband signal, electronic noise, temperature conditions, and general measurement error; the results show that the 2-D FDTD does an impressive job of modeling the electric field while maintaining the characteristics of the real electric field. Although the differences between the measured and calculated signals may be greater than the expected variations due to buried targets, the FDTD calculation captures the effects of rough dispersive ground as well as relative changes due to buried targets.

Conclusions

The approach of simulating the clutter response of realistic soil for an existing high-performance impulse GPR using relatively simple 2-D FDTD calculations has been demonstrated. The radiated fields generated using a high resolution 3-D FDTD within a small box surrounding the antenna element are sampled along the line segment of the incidence plane, decomposed into TE and TM components, and then propagated with a coarse 2-D FDTD dispersive soil model. The waves incident on the receiver are then convolved with the transfer function of the receiving antenna to give the received signal.

Computed results compared well to experimentally measured signals using the Geo-Centers TEMR antenna transmitter/receiver pairs. The simulated output voltages are close to those obtained from experiment, with similar pulse shape. Despite slight quantitative differences between the modelled and experimental data, 2-D FDTD has been shown to simply and successfully simulate scattering by rough dispersive ground.

To address scattering from finite 3-D buried targets, it is anticipated that another 3-D simulation of the sub-volume surrounding and including the target would be required. For shallow buried targets, the target volume could include the ground surface as well. Thus, the simulation could be divided into 3-D models of the transmitting antenna, the target and the receiving antenna, with 2-D simulation of the intervening space. Multiple

interactions between the antenna and the target tend to be small, especially for buried targets, so this division will not introduce much modeling error.

Acknowledgments

The authors thank Arnold Dean of Geo-Centers, Inc. for providing the experiment data and the numerical information to obtain the antenna system transfer function, and Dongping Jin for providing dispersion parameters of Puerto Rican clay loam soil. Abstract

In this paper we present an algorithm for the detection and localization of an unknown number of objects present in the near field of a linear receiver array. To overcome the nonplanar nature of the wavefield over the array, the full array is divided into a collection of sub-arrays, such that the scattered fields from objects are locally planar at each sub-array. Using the MUSIC algorithm, directions of arrival (DOA) of locally planar waves at each sub-array are found. By triangulating these DOAs, a set of crossings, condensed around expected object locations, are obtained. To process this spatial crossing pattern, we develop a statistical model for the distribution of these crossings and employ hypothesis testing techniques to identify a collection of small windows likely to contain targets. Finally, the results of the hypothesis tests are used to estimate the number and locations of the targets. Using simulated data, we demonstrate usefulness and performance of this approach for typical background electrical properties and signal to noise ratios.

1 Introduction

The problem of detection and localization of objects in the near field of an antenna array has arisen in a number of application areas in recent years. For example, in the area of landmine remediation, the goal is to find relatively small, metallic and plastic objects located in a lossy medium (the soil) but a few centimeters from the transmitters and receivers. Alternatively, for purposes of environmental remediation, the targets of interest tend to be larger (eg. steel metal drums filled with hazardous waste), and located on the order of meters from the array. Although several near-field array processing methods have been reported in the literature, their use has been restricted to the localization of independent sources radiating spherical waves [1–3] and are thus not suited to the problem of interest in this work: the detection and localization of extended targets illuminated by an incident plane wave and positioned such that multiple scattering effects cannot be ignored.

The problem of target detection and localization for these and related applications often is addressed by using the data to produce a pixel-by-pixel map of the region near the array and then post-processing the image to localize the objects [4–8]. Since the initial image generation represents an ill-posed inverse problem, a stable solution requires the use of a regularization method [9]. Unfortunately, typical regularizers result in smooth images thereby making the detection all the more difficult. In this paper, we develop an alternate approach to target detection and localization which bypasses this difficult step of image generation and is aimed at extracting the number of objects and their locations more directly from the data.

Of particular interest is the measurement geometry shown in Fig. 1. A plane wave illuminates the region of interest assumed to be a homogeneous, possibly lossy medium containing one or more targets located in the near field of an array of receivers. The inherent array structure of

the measurement geometry suggests that the high resolution array processing techniques [10, 11] quite popular in the signal processing community would be well suited for the near-field detection problem. Adapting such methods to the problem of interest here presents a collection of interesting challenges. First, these array processing techniques typically assume that the sources are infinitely far away so that the waveform received on the array is planar. For our problem, since the objects are located relatively close to the receiver array, this key assumption is not valid. Second, for such near-field objects both range as well as the direction of arrival has to be determined in order to localize the object. Finally, a problem common to both the near-field and far-field array processing algorithms is that the number of incident waveforms/targets is not known *a priori*.

To deal with the nonplanar nature of the wavefronts over the array, we partition the receiver array into sub-arrays, such that the scattered field is locally planar at each sub-array. Then, using high resolution array processing techniques, each sub-array identifies a single direction of arrival (DOA) corresponding to the most dominant scatterer in the vicinity of that sub-array. The localization of the objects in terms of their ranges and bearings is achieved by triangulating the directions of arrival from all subarrays which in turn results in a crossing pattern of DOA intersections. Examination of typical crossing structures reveals that there are two distinct patterns where the crossings are either dense or sparse. Dense crossing regions clearly indicate object locations and are distinguished from “background” regions where the crossings are sparse. The problem of object detection and localization then is reduced to the processing of the crossings obtained from our triangulation procedure.

For this purpose, we introduce a simple yet accurate stochastic model describing the spatial distribution of DOA crossings. Such modeling is warranted for two reasons. First, due to the noise in the data, the DOA intersection points are inherently randomly distributed in the plane. Second,

such modeling forms a solid basis for algorithm development and quantitative performance analysis in the form of detection and false alarm rates.

In this work, we model the two classes of crossings (dense vs. sparse) using a pair of spatial Poisson distributions [12]. The Poisson model in the target region has a large rate parameter while that of the background region is considerably smaller. Based on these target and background models, we develop a hypothesis testing technique for the joint estimation of the rate parameters and the localization of dense crossing regions which indicate the existence of targets. Simple post-processing of the hypothesis testing results provides both the number of targets and estimates of their locations. Finally, we verify that the a Poisson model is in fact a rather accurate description of the spatial distribution of crossings.

We demonstrate the performance of this approach for the detection and localization of multiple mine-like and drum-like targets located in the near field of the receiver array. For mine-like targets relative positions of the objects are changed to see the effect of object geometry on detectability. We show that the detectability improves, and false alarm rate decreases as the objects are located far apart. For drum-like targets, we demonstrate the effect of relative depth as well as relative distance between objects on detectability.

The remainder of this paper is organized as follows. In Section 2 we describe the models and notation used in the paper, in Section 3 we introduce the detection algorithm and hypothesis testing. Examples depicting performance of the algorithm are given in Section 4 and in Section 5 we will draw conclusions and suggest future work.

2 Background

The multi, bi-static measurement scheme depicted in Fig. 1 is considered in this paper. A perpendicularly polarized plane wave, $E_i(\mathbf{r})$, impinges on a collection of objects in a known background, inducing surface and volume currents which in turn radiate a scattered field, $E_s(\mathbf{r})$ ¹. The scattered electric field from the targets is spatially sampled by a uniformly spaced, N -element linear array with isotropic receiver characteristics. The measured data at the sensor outputs are:

$$\mathbf{x} = \mathbf{E}_s + \mathbf{n}, \quad (1)$$

where $\mathbf{E}_s = [E_s(\mathbf{r}_1) \ E_s(\mathbf{r}_2) \ \cdots \ E_s(\mathbf{r}_N)]^T$, \mathbf{r}_i is the vector from the origin to the i th receiver location and \mathbf{n} is zero mean, white Gaussian noise.

The structure of the receivers in Fig. 1 coupled with the underlying problem of target detection suggests the use of array processing methods for localizing buried targets. In this paper we consider the MUSIC (Multiple Signal Classification) [13] algorithm. Traditionally, MUSIC and other direction finding techniques are used to determine directions of arrival (DOA) of plane waves to a receiver array. Here, we adapt MUSIC to the near-field detection problem.

To make use of the MUSIC algorithm, the experiment as represented by (1) is repeated many times to determine the statistics of \mathbf{x} . In particular, if L scattering experiments are performed, then the maximum likelihood estimate of the spatial autocovariance matrix \mathbf{R} is given by [10]:

$$\hat{\mathbf{R}} = \frac{1}{L} \sum_{l=1}^L \mathbf{x}_l \mathbf{x}_l^H \quad (2)$$

where \mathbf{x}_l is the data measured at the l th experiment, and superscript H denotes conjugate transpose.

Then, the eigenspace decomposition of $\hat{\mathbf{R}}$ yields [10]:

$$\hat{\mathbf{R}} = \hat{\mathbf{U}}_s \hat{\mathbf{\Lambda}}_s \hat{\mathbf{U}}_s^H + \hat{\mathbf{U}}_n [\hat{\sigma}^2 \mathbf{I}] \hat{\mathbf{U}}_n^H \quad (3)$$

where $\hat{\mathbf{U}}_s$ is the estimated signal subspace matrix and contains the M signal eigenvectors, and $\hat{\mathbf{U}}_n$

¹All analysis is in frequency domain, thus the $e^{j\omega t}$ dependence is suppressed

is the estimated noise subspace matrix and contains $N - M$ noise eigenvectors of multiple noise eigenvalue $\hat{\sigma}^2$. The projection operator onto the noise subspace is defined as [10]:

$$\hat{\Pi}_{\mathbf{n}} = \hat{\mathbf{U}}_n \hat{\mathbf{U}}_n^H. \quad (4)$$

Assuming plane wave incidence on the array, the idea behind MUSIC is that the reciprocal of the “distance” between the estimated noise subspace and the true noise subspace has sharp peaks around the DOAs. Thus, if one plots this quantity versus all possible angles, estimates of DOAs can be determined by the maxima of the resulting angular spectrum which is given by [10]:

$$P_{MUSIC}(\theta) = \frac{\mathbf{a}(\theta)^H \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \hat{\Pi}_{\mathbf{n}} \mathbf{a}(\theta)} \quad (5)$$

where $\mathbf{a}(\theta) = [1 \quad e^{j\beta d \cos \theta} \quad e^{j2\beta d \cos \theta} \quad \dots \quad e^{j(N-1)\beta d \cos \theta}]^T$ is the direction vector, β is the wave number in the medium of propagation, and d is the distance between two receivers.

As stated previously this formulation of the array processing problem assumes that the radiator is infinitely distant so that the scattered field has planar wavefronts and the elements of the direction vector $\mathbf{a}(\theta)$ are complex exponentials. However for the problems of interest here, the receivers are in the near-field region of the radiating sources, resulting in non-planar wavefronts. Additionally, the target localization problem not only requires the DOA relative to the array but also the range of the target from a point on the array (eg. the leftmost element.)

3 Algorithm

A key element of the work in this paper is the development of a sub-array processing method for detection of multiple objects in the near field of an array. In a previous work [14], we have examined such a technique for detection and localization of single metallic and dielectric objects. As illustrated in Fig. 2 (and as is generally the case), the localization problem in [14] is straightforward since typically all crossings are densely packed within the radius of the object. Therefore, the location of the object can be inferred quite easily. For multiple objects, however, the crossing pattern is

quite complicated, since DOAs of different objects create unwanted crossings as shown in Fig. 3. The clusters of object crossings are embedded in this unwanted background crossings, and have to be extracted carefully. Thus, in this work, we concentrate exclusively on the problem of multiple object detection.

Before introducing the details of our approach, we want to briefly describe the algorithm with the help of flow chart in Fig. 4. The algorithm proceeds as follows:

1. **Sub-array processing:** At this stage of the algorithm, we partition the receiver array so that the observed scattered field is locally planar at each sub-array. The directions of arrival (DOAs) are found using MUSIC as if planar waves are impinging on the sub-arrays. The DOAs are then triangulated to obtain the crossing pattern. This stage of the algorithm is repeated several times for plane waves at different temporal frequencies to improve performance and resolution. The crossing patterns obtained at different frequencies are overlaid to yield an aggregate crossing pattern which is, then, passed onto the second stage of the algorithm.
2. **Crossing analysis:** In the second stage, the crossing pattern is modeled with two Poisson counting processes, corresponding to target and background regions. After estimating the required rate parameters using the crossing data, a hypothesis testing procedure is employed to determine a set of “window” regions corresponding to areas containing targets.
3. **Target extraction:** At the final stage of the algorithm, the individual detection windows are aggregated into a number of spatially disjoint groups. The total number of groups indicates the estimated number of targets, and average coordinates of all windows in a group indicate the estimated center of the corresponding target.

3.1 Sub-array Processing

The direction finding algorithms traditionally assume plane wave incidences and determine the DOA associated with each plane wave. For near-field problems, however, both DOA and the range of the source (in our case scatterer) should be acquired. Here, we describe a sub-array processing (SAP) scheme which only requires one-dimensional search in DOA space of each sub-array. The idea behind the sub-array processing is that if the aperture of the sub-array is small enough, the scattered field impinging upon it can be assumed locally planar. Thus, the plane wave MUSIC can be used to find DOAs at each sub-array, and by triangulation, it is possible to localize the scatterers.

When there are $M > 1$ objects in the vicinity of the array, we have two options in terms of how MUSIC is employed:

1. Each sub-array finds M DOAs for all locally planar waves scattered from M objects, or
2. Each sub-array finds one DOA for the locally planar wave dominant in the total scattered field (Fig. 3 shows $M = 2$ case).

Given M objects and S sub-arrays, for each operating frequency the first and second options result in $0.5SM(SM - 1)$ and $0.5S(S - 1)$ crossings, respectively. The first option creates many unwanted crossings when DOAs belonging to different objects intersect. In addition, we have to know the number of objects under the array to use this option. On the other hand, the second option does not require the knowledge of number of objects, and the scattered fields from targets closer to the sub-arrays, particularly in a lossy medium such as soil, dominate the total scattered field at the sub-arrays. Therefore, the latter option seems more practical especially when one wants to avoid estimating the number of scatterers first, and is used in the remainder of this paper.

Once one DOA at each sub-array is determined, all DOAs are triangulated to estimate the target locations. Fig. 3(a) shows the triangulation of DOAs, and (b) shows the crossings. In contrast to the single object case, for multiple objects, the crossing pattern may get quite complicated since DOAs belonging to different objects also intersect each other to create unwanted crossings. Thus, a second level of processing is required to extract the clusters indicating the estimated object centers.

3.2 Crossing Analysis

In this section we present an approach that models the DOA crossings with Poisson point processes. Inspecting Fig. 3(b), we see two distinct regions where the density of the crossings are quite different: in the first region (*background region*) the crossings are sparse, and in the second region (*target region*) the crossings are dense. By exploiting this difference, it is possible to isolate target locations. Hence, we introduce a Poisson model for DOA crossings which has a large rate parameter (intensity) in target regions and a small rate parameter in the background region.

Formally, for a given crossing pattern, we count the number of crossing Y_j , $j = 1, 2, \dots, N_y$, in a window of size $w_x \times w_y$, where N_y is the total number of *non-overlapping* windows, w_x and w_y are the width of the windows in x and y directions, respectively. The windows must be non-overlapping to guarantee the independence of random variables Y_j .

In order to ensure that Y_j is Poisson distributed, we tested for fitness to Poisson distribution by using the graphical technique presented in [15]. The technique proposes that for each count k observed in Y_j , we plot k versus $(\ln k! + \ln F_k)$ where $F_k = \sum_{j=1}^{N_y} [Y_j = k]$ is the number of data values Y_j equal to k . If the fit to the Poisson model is satisfactory, then the plot should form a straight line with slope approximately $\ln \lambda$, where λ is the rate parameter of the distribution. When we apply this test to a typical crossing pattern, instead of a straight line, we observed the curve in Fig. 5. By examining this curve, we notice that it can be decomposed into two parts, each roughly

corresponding to a straight line. The first part is when the crossing count k is small (between 0 and 2), and the second part is when k is large (greater than 3.) It is clear that these two regions correspond to the background process which is expected to have a small count of crossings, and the target process which is expected to have a large count of crossings. Furthermore, using these two approximately linear regions, we can decouple background and target processes by identifying k_b and F_{kb} for the background, and k_t and F_{kt} for the target regions where $k_b = 0, 1, 2$, $k_t = 3, 4, \dots$, $F_{kb} = \sum_{j=1}^{N_y} [Y_j = k_b]$ and $F_{kt} = \sum_{j=1}^{N_y} [Y_j = k_t]$. Then, the rate parameters for the background and the target regions are given by their maximum likelihood estimators [15]:

$$\hat{\lambda}_b = \frac{1}{N_b} \sum_{k_b=0}^2 k_b F_{kb}, \quad (6)$$

and

$$\hat{\lambda}_t = \frac{1}{N_t} \sum_{k_t=3}^{\infty} k_t F_{kt}, \quad (7)$$

where $N_b = \sum_{k_b} F_{kb}$ and $N_t = \sum_{k_t} F_{kt}$. Having estimated $\hat{\lambda}_b$ and $\hat{\lambda}_t$, the probability mass functions in the background and target regions can be expressed as:

$$f_X(k|\text{Background}) = P\{X = k|\text{Background}\} = \frac{1}{k!} e^{-\hat{\lambda}_b} \hat{\lambda}_b^k \quad (8)$$

and

$$f_X(k|\text{Target}) = P\{X = k|\text{Target}\} = \frac{1}{k!} e^{-\hat{\lambda}_t} \hat{\lambda}_t^k. \quad (9)$$

To extract crossing clusters, we sweep the region of interest with a test window of size $w_x \times w_y$. It is important that the area of the test window is equal to the area of the non-overlapping windows used in estimating the rate parameters. At each location of the test window, we count the number of crossings T_j , $j = 1, 2, \dots, N_{test}$, where N_{test} is the total number of *overlapping* sweep windows in the region of interest. The number of overlapping test windows N_{test} defines the resolution of detection, and it is greater than N_y . Since we are going to test each T_j against the hypothesis one by one, the use of overlapping windows is allowed. Hypothesis test permits us determine whether

the test window is over a background region or over a target region. The hypothesis test is then formally written as:

- H_0 : T_j is Poisson distributed with a small rate parameter $\hat{\lambda}_b$,
- H_1 : T_j is Poisson distributed with a large rate parameter $\hat{\lambda}_t$.

Based on this hypothesis test, if H_0 is true, we decide that the window belongs to a background process with a small intensity. However, if H_1 is true, we declare that the window belongs to a target process with a large intensity and call it a detection.

The likelihood ratio for the hypothesis test is formed in terms of the probability mass functions of (8) and (9) as:

$$\Lambda(T_j) = \frac{f_X(T_j|H_1)}{f_X(T_j|H_0)}$$

The decision is, then, made based on the test:

$$\ln\{\Lambda(T_j)\} = T_j \stackrel{H_1}{>} K,$$

where the decision threshold, K , is found from a specified false alarm rate P_{fa} using (10). This means that all windows which has K or more crossings in them will be declared as target locations.

Probability of false alarm P_{fa} can be written in terms of the decision threshold K and probability mass function of background process in (8) as :

$$P_{fa} = \sum_{k=K}^{\infty} f_X(k|H_0). \quad (10)$$

Given the decision threshold K , the probability of detection for the Poisson model developed in this section is given by:

$$P_d = \sum_{k=K}^{\infty} f_X(k|H_1). \quad (11)$$

It might be argued that since target windows are obtained via thresholding, there would be no need for a Poisson-based model as described in this section. A plain thresholding scheme on DOA

crossings would also locate the targets successfully. However, the Poisson model provides a solid groundwork for a detailed statistical analysis. With the model, it is possible to define probabilities of false alarm and detection. Based on these statistical analyses, it is possible to make educated predictions about the performance of the system under different conditions.

3.3 Target Extraction

Hypothesis testing with the Poisson model results in detection windows as shown in Fig. 6. By looking at this figure, a human operator may conclude the target locations and their numbers. However, we want the detection algorithm to do these decisions and calculations for us automatically. In effect, we want the algorithm to yield the number of targets in the region of interest and their estimated locations, rather than the intertwined pattern of detection windows.

The pattern of detection windows suggests that the detection windows belonging to the same targets overlap. Therefore, we classify the detection windows so that all overlapping windows form a different group. The number of targets is, then, equal to the number of groups and the estimated object centers are obtained by averaging the coordinates of the windows in each group. The grouping algorithm we use, therefore, proceeds as follows. Start with the first window on the list of detection windows and place it in the first group. For each of the other windows, test if they overlap with any window in the k th group for $k = 1, 2, \dots, G_c$, where G_c is the number of currently available groups. If the window overlaps with only one group, add it to that group. If the window overlaps with more than one groups, merge those groups, and reduce the number of current groups G_c accordingly. If the window does not overlap with any windows among G_c groups, then form $(G_c + 1)$ th group with that window. When all detection windows are classified, G_c gives the number of objects, and averaged coordinates of all windows in each group give the estimates of center of the objects they represent.

3.4 Frequency Diversity

Frequency diversity is often used in detection applications for two important reasons: to increase the resolution (high frequencies) and to allow radar signals to penetrate deeper into the medium (low frequencies). Therefore, with a wide frequency range, one can ideally get more resolution in the vicinity of the radar, and more penetration to probe deeper objects. To take advantage of these benefits, we use the sub-array processing in a multi-frequency scheme. For each frequency the sub-array processing described in Section 3.1 is carried out to obtain the DOAs and the crossing pattern. Then, these multiple crossing patterns are overlaid to give an aggregate crossing pattern which is modeled as Poisson counting processes in Section 3.2.

4 Examples

In this section, we present applications of sub-array processing to the detection of multiple mine-like and multiple drum-like objects. In order to simplify the scattering phenomenon associated with the detection problem, both mine-like and drum-like objects are modeled with simple, circular objects. The system parameters for both applications are kept constant to provide a better comparison of the method between applications. In order to introduce frequency diversity, the objects are illuminated with plane waves at three different frequencies: 1.2, 1.0 and 0.8 GHz. The frequency range used is typical of that used in practical subsurface sensing systems. The scattered field is observed along a 33-element, uniform, linear receiver array which spans an aperture of 1.5 m. The sensors are assumed to be ideal, isotropic receivers, and the inter-element spacing of the receivers are chosen such that it is less than half a wavelength for the soil characteristics [16] at the frequencies used. The receiver array is divided into 11 three-element sub-arrays for the processing. The objects are placed in a lossy, homogeneous background which has the same electrical

characteristics of 5% moist San Antonio clay loam or 10% moist Puerto Rico clay loam ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} \text{ S/m}$) at around 1.0 GHz [16].

For the simulations, the definition of signal to noise ratio (SNR) is not obvious. In practical problems, SNR is imposed by the nature of the system noise. However, in computer simulations we want to reference the noise power to a fixed quantity that does not change as the positions of the objects change. For this purpose SNR is referenced to the scattered field strength of a single, cylindrical, metallic object placed at the same depth as the objects, in the same lossy medium. The radius of the reference scatterer is the same as the radii of the targets. With this definition, the noise power is always proportional to the power of reference scattered field, not the power of field scattered from targets which changes as the positions of objects change.

In all examples the exact scattered field due to multiple objects embedded in a homogeneous, lossy background is calculated using the recursive T-matrix algorithm [17–20] to keep the computational requirements at reasonably low levels.

4.1 Multiple Mine-like Objects

In these examples, we placed two mine-like objects, each with 7.5 cm. diameter, 15 cm. under the receiver array. Even though the algorithm is capable of detecting more than two objects, it seems that for practical purposes no more than two mines will be placed in the array’s aperture of 1.5 meters. We have not explored the performance of the processing with respect to depth assuming that mine-like objects will be placed at uniform depths under the array.

The first example demonstrates the utility of the sub-array processing in detecting and localizing both a metallic and a dielectric object in the same medium. For this purpose, a metallic object and a dielectric object with dielectric constant of 2.5 are placed at $(20, -15)$ cm and $(80, -15)$ cm, respectively, in the homogeneous background described before, Fig 6. Signal to noise ratio is fixed

at 10 decibels. Fig 6 shows the directions of arrivals, and detection windows when probability of false alarm is 10^{-8} , which corresponds to a crossing threshold of $K = 7$. The two circles in this figure denote the objects, and the intertwined squares, due to overlaps in test windows, depict the estimated target windows. The detection windows are then used in the grouping algorithm described in Section 3.3. As expected two distinct groups of overlapping windows indicated that there are two objects beneath the array. The estimated center for the objects are found to be $(19.52, -14.02)$ cm and $(80.10, -14.82)$ cm. Consequently, both metallic and dielectric objects are detected within acceptable estimation error margins.

Next, we consider an example that demonstrates the detectability of objects and the performance of SAP as relative positions of the objects change. In this example, both objects are assumed to be metallic in order to see the influence of relative distance between same type of objects on detectability and estimation error. For this purpose, we fixed the location of the first object at $(x, y) = (-40, -15)$ cm. The other one is moved from $x = 0$ cm to $x = 125$ cm in the lateral direction while its depth is kept at the same level as the fixed object, Fig. 7. The signal to noise ratio is assumed to be 30 decibels.

With this geometry, the moving object is always located under the array, and thus detected for all combinations of relative positions. Detection of the fixed object, on the other hand, is challenging since it lies outside the span of the array. Fig 8 shows the average simulated probability of detection of the fixed object over 100 Monte-Carlo simulations as the other object is moved under the array when probability of false alarm is set to 10^{-3} . As it is clear from this figure, the fixed object can be detected only if the other object is well away from it. The fixed object may also be detected with less than 10% probability when the moving object is located between $x = 0$ and $x = 20$ cm. This is due to the fact that for these relative locations, both objects are close enough so

that DOAs belonging to the moving object create crossings around the fixed object as well as the moving object. In fact, because of this effect, the region between the two objects is incorrectly detected as targets, and thus false alarm rate is large when relative distance between two objects is small, Fig. 9. Simulated $P_{fa, sim}$ as depicted in Fig. 9 approaches to the false alarm rate set at the beginning of the simulation (dashed line), as the relative distance between the objects increase.

We have also investigated the effect of relative distance on estimated object centers. For this purpose, we plotted the averaged estimation error in x -direction ($\Delta x = x_{true} - x_{estimated}$) versus the averaged estimation error in y -direction ($\Delta y = y_{true} - y_{estimated}$) for both fixed and moving objects in Fig. 10(a-b). The estimated object coordinates are obtained by averaging 100 Monte-Carlo simulations. The dashed circles indicate the boundaries of the objects. The closer the symbols (o's or \diamond 's) are to the center, the smaller is the estimation error. Since the moving object is always detected, each small circle in Fig. 10(a) corresponds to a different position of the moving object. As seen from this plot, the estimation error of the moving object is only a small fraction of the radius. Small circles outside the object boundary (dashed circle) correspond to locations where the moving object is close to the fixed object. Each small circle and diamond in Fig. 10(b) corresponds to a relative position when the fixed object is detected. The small circles denote the error in estimated centers when the moving object's x -coordinate is greater than 95 cm, and small diamonds correspond to other locations of the moving object for which the fixed object is detected. The loci of small circles and diamonds clearly imply that as the relative distance between the objects gets larger, the estimation error in the position of the fixed object gets smaller.

4.2 Multiple Drum-like Objects

In this section, two drum-like objects, each with 50 cm. diameter, are placed at various depths from the receiver array. Since drums are made up of metals, the objects are assumed to have

infinitely large conductivity. The signal to noise ratio is set at 10 decibels. The detection windows for a typical case is shown in Fig. 11. In this example one object is at $(-40, -125)$ cm and the other is at $(140, -125)$ cm, while the lossy, homogeneous background is the same as previous example. The threshold of detection corresponding to a false alarm rate of 10^{-8} is found to be $K = 6$. Fig. 11(b) depicts the detection windows obtained after hypothesis testing. These windows are then processed by the grouping algorithm of Section 3.3. As expected, there found to be two overlapping window groups which imply that there are two objects in the region of interest with centers located at $(-40.02, -111.70)$ cm and $(139.93, -108.46)$ cm.

As the second example of this section, we considered keeping one of the objects at a fixed location, and moving the other object around below the array. The first object is fixed at $(-40, -125)$ cm, and the other is moved from $x = 40$ cm to $x = 240$ cm in the lateral direction at two different depths, -125 cm and -137.5 cm, Fig. 12. The SNR is set to 30 dB. Contrary to mine-like object example, in this case the fixed object is at an advantageous location and detected with a probability of 1.0 regardless of the position of the moving object in the defined region. The moving object is hard to detect, since it is placed either outside the span of the array most of the time or deeper than the fixed object. Fig. 13 depicts the average probability of detection of the moving object over 100 Monte-Carlo simulations for two depths when probability of false alarm is set to 10^{-3} . It is clear that as the moving object is placed far from the array, it is less likely to be detected. Relative to the depth of the fixed object, if the moving object is placed deeper, it has to be nearer to the array to be detected. Simulated probability of false alarm ($P_{fa,sim}$) for this example is zero for all positions of the moving object, since both objects are relatively far apart to cause a false detection window.

We have also investigated the effect of relative distance and depth on estimated object centers.

For this purpose, we plotted the estimation error in x -direction ($\Delta x = x_{true} - x_{estimated}$) versus the estimation error in y -direction ($\Delta y = y_{true} - y_{estimated}$) for both fixed and moving objects for two depths in Fig. 14(a-b). The estimated object coordinates are obtained by averaging 100 Monte-Carlo simulations. The dashed circles indicate the boundaries of the objects. Circles shows the estimation errors when both objects are at the same depth, and diamonds show those when the moving object is a half radius deeper than the fixed object. Symbols (circle/diamond) inside the dashed circle indicate the estimation errors less than the radius of the object. In Fig. 14(a-b) it is observed that as the moving object gets far from the array, the estimation error in position of moving object increases, and that in position of fixed object becomes smaller. Placing the moving object at a deeper location increases the estimation error in its position, and slightly improves that in fixed object's position.

5 Conclusions

In this paper we present an algorithm that can detect and localize an unknown number of objects in the near field of a linear sensor array. The issues related to near-field scattering are overcome by partitioning the full array into sub-arrays so that the non-planar scattered field becomes locally planar at each sub-array. DOAs corresponding to these locally planar waves are then determined using array processing techniques. Triangulation of such DOAs results in dense and sparse regions of crossings which are modeled with a pair of spatial Poisson distributions. Estimated object locations, and the number of objects are finally obtained by applying a hypothesis test to Poisson models and then extracting groups of spatially disjoint detection windows.

We demonstrate the performance of the algorithm using simulated data. The usefulness of this algorithm is exhibited for both mine-like and drum-like objects. For mine-like targets, we show that

the algorithm can detect and localize multiple targets with different electrical properties. Then, we demonstrate the detectability of such objects when relative distance between them changes. We conclude that the detectability improves as the objects are located farther from each other while staying within a reasonable distance from the array. In addition, it is shown that theoretical and simulated probabilities of false alarm and detection are in agreement. For drum-like targets, we demonstrate the usefulness of the algorithm for detection and localization of multiple objects. Furthermore, the effect of relative distance and relative depth on detectability is treated. Results of this analysis supports the results obtained for mine-like objects.

As the future work, we want to combine the algorithm of this paper with the matched field processing (MFP) adapted for near-field object detection in [14]. The MFP is known for its accuracy and when used in tandem with the SAP, where SAP supplies rough estimates of object positions to MFP, it would be possible to localize closely located objects. The combined algorithm would inherit the best merits of both algorithms, viz. speed and efficiency of SAP and accuracy of MFP.

ABSTRACT

In recent years there has been considerable interest in the use of ground penetrating radar (GPR) for the non-invasive detection and localization of buried objects. In a previous work, we have considered the use of high resolution array processing methods for solving these problems for measurement geometries in which an array of electromagnetic receivers observes the fields scattered by the subsurface targets in response to a plane wave illumination. Our approach uses the MUSIC algorithm in a matched field processing (MFP) scheme to determine both the range and the bearing of the objects.

In this paper we derive the Cramer-Rao bounds (CRB) for this MUSIC-based approach analytically. Analysis of the theoretical CRB has shown that there exists an optimum inter-element spacing of array elements for which the CRB is minimum. Furthermore, the optimum inter-element spacing minimizing CRB is smaller than the conventional half wavelength criterion. The theoretical bounds are then verified for two estimators using Monte-Carlo simulations. The first estimator is the MUSIC-based MFP and the second one is the maximum likelihood based MFP. The two approaches differ in the cost functions they optimize. We observe that Monte-Carlo simulated error variances always lie above the values established by CRB. Finally, we evaluate the performance of our MUSIC-based algorithm in the presence of model mismatches. Since the detection algorithm strongly depends on the model used, we have tested the performance of the algorithm when the object radius used in the model is different from the true radius. This analysis reveals that the algorithm is still capable of localizing the objects with a bias depending on the degree of mismatch.

1. INTRODUCTION

Non-invasive detection and localization of buried objects using ground penetrating radar (GPR) type geometries have been of interest to many researchers in recent years. Some of the most promising application areas for this technology include mine detection and hazardous waste remediation.

In subsurface object detection most often a pixel-by-pixel map of the region of interest is produced and the detection is then made by post-processing the image [1–3]. However, since this inverse problem is inherently ill-posed, the image-then-detect approach is quite sensitive to noise. While the ill-posedness can be off-set through regularization [4], typical regularization methods result in smooth images thereby making the detection all the more difficult. On the other hand, making use of the fact that the ultimate goal of the problem is the localization of objects with known structures, we can reparameterize the problem within an object-based detection framework [5–7]. Rather than looking for a large number of pixels, we extract the information about a small number of unknowns from the data: specifically the coordinates of the buried objects. By constraining the degrees of freedom in this manner, ill-posedness is substantially reduced and the resulting algorithms prove to be robust to noise.

The inherent array structure of GPR measurement geometry in Fig. 1 suggests that the high resolution array processing techniques [8], in particular, multiple signal classification (MUSIC) algorithm [9], quite popular in the signal processing community would be well suited for the subsurface detection problem. However, direction finding array processing techniques assume that the sources are infinitely far away so that the waveform received on the array is planar. For subsurface object detection case, on the other hand, the objects are located relatively closer to the receiver array, thus the scattered field from these objects across the array is not planar. In addition, for such near field objects, range as well as the direction of arrival has to be determined in order to localize the object. In ocean acoustics, the matched field processing (MFP) [10] has been successfully used for localization of sources modeled as point radiators. MFP is an array processing technique that uses the spatial complexities of the fields to localize sources, and thus allows for estimation of both the range and the bearing of the objects. Recently, MFP has been adapted to other application areas such as stratospherical electromagnetics [11], acoustics [12], and subsurface object detection [13]. In [13], we have demonstrated that MUSIC-based MFP can be used to detect and localize simple shaped metallic and dielectric objects over a wide range of soil characteristics and signal to noise ratios quite accurately.

In this paper, we extend the results of [13] to include the performance analysis for the matched field processing. Since we use a model based approach, it is imperative to know the performance of the algorithm against changes in problem parameters. For this purpose, we derive the Cramer-Rao performance bound for an unbiased estimator of the object position similar to derivations in [14]. Analytical bounds of range and bearing variables are then validated by running Monte-Carlo experiments for two estimators. The first one is MUSIC-based MFP described in [13], and the second one is the maximum likelihood (ML) based MFP. We observe that asymptotically MUSIC and ML estimators perform very similarly as reported in [14]. In addition, plotting the analytical CRB against the array length with fixed number of receivers reveals that there are optimal array lengths for estimating the range and bearing of an object, which minimizes the lower bound. Therefore, if one aims to determine the target's range or bearing with minimum variance, there exists an optimal array length, corresponding to an optimal inter-element spacing. Finally, we show the sensitivity of model mismatch on object radius by using a different radius in MFP model than the true radius of the object. This analysis demonstrates that under model mismatches, MFP can still localize the objects with a bias dependent on the degree of mismatch.

The remainder of the paper is organized as follows. In Section 2, we introduce the problem geometry, and brief overview of plane wave MUSIC. In Section 3, we review the matched field processing for subsurface

Figure 1. Problem geometry

detection problems. The Cramer-Rao lower bound for MFP is derived in Section 4. Numerical examples are presented in Section 5, and in Section 6, conclusions will be drawn and future directions will be presented.

2. PROBLEM GEOMETRY AND BACKGROUND

The ground penetrating radar (GPR) type measurement scheme depicted in Fig. 1, is considered in this paper. The objects are buried in a background for which the constant electrical characteristics (relative permittivity and conductivity) are assumed known. A transverse magnetic (TM) polarized plane wave, $E_i(\mathbf{r})$, impinges on the objects, inducing surface and volume currents which in turn radiate a scattered field, $E_s(\mathbf{r})^\dagger$. An important assumption in our approach is that the material properties and the shapes of the objects are known a priori. The scattered electric field from these objects is spatially sampled by a uniformly spaced, linear array with isotropic receiver characteristics. The measured data at the sensor outputs are:

$$\mathbf{y} = \mathbf{E}_s \mathbf{x} + \mathbf{n}, \quad (1)$$

where $\mathbf{E}_s = [E_s(\mathbf{r}_1) \ E_s(\mathbf{r}_2) \ \cdots E_s(\mathbf{r}_N)]^T$, \mathbf{r}_i , $i = 1, 2, \dots, N$, is the vector from the origin to the i th receiver location and \mathbf{n} is spatially and temporally white Gaussian noise. If M objects scatter the incident field, then \mathbf{E}_s becomes an $N \times M$ matrix with each column formed by the scattered field due to a different object. For time domain applications, the vector \mathbf{x} contains the time variations. Since we do our analysis in the frequency domain, and suppress $e^{j\omega t}$, $\mathbf{x} = 1$ for multiple scatterers, and $x = 1$ for single object. For the sake of simplicity, this paper deals with the case where there is only one scatterer in the region of interest. Thus, the data model can simply be written as:

$$\mathbf{y} = \mathbf{E}_s + \mathbf{n}. \quad (2)$$

The structure of the receivers in Fig. 1 coupled with the underlying problem of target detection suggests the use of array processing methods for localizing buried targets. In this paper we consider the MUSIC (Multiple Signal Classification) [9] algorithm. Traditionally, MUSIC and other direction finding techniques

[†]All analysis is in frequency domain, thus the $e^{j\omega t}$ time dependence will be dropped.

are used to determine the directions of arrival (DOA) of plane waves to a receiver array. In the rest of this section, we will briefly review the plane wave MUSIC.

The experiment as represented by the data model in (1) is repeated many times in order to determine the statistics of \mathbf{y} . In particular, if L experiments are performed, then the maximum likelihood estimate of the spatial autocovariance matrix $\mathbf{R} = E\{\mathbf{y}\mathbf{y}^H\}$ is given by:

$$\hat{\mathbf{R}} = \frac{1}{L} \sum_{l=1}^L \mathbf{y}_l \mathbf{y}_l^H \quad (3)$$

where \mathbf{y}_l is the data measured at the l th experiment, and superscript H denotes conjugate transpose. The sample covariance matrix $\hat{\mathbf{R}}$ is used in MUSIC algorithm to separate signal and noise subspaces through the eigenspace decomposition [8]:

$$\hat{\mathbf{R}} = \hat{\mathbf{U}}_s \hat{\mathbf{\Lambda}}_s \hat{\mathbf{U}}_s^H + \hat{\mathbf{U}}_n [\hat{\sigma}^2 \mathbf{I}] \hat{\mathbf{U}}_n^H \quad (4)$$

where $\hat{\mathbf{U}}_s$ is the estimated signal subspace matrix and contains the M signal eigenvectors, and $\hat{\mathbf{U}}_n$ is the estimated noise subspace matrix and contains $N - M$ noise eigenvectors of multiple noise eigenvalue $\hat{\sigma}^2$. The projection operator onto the noise subspace is defined as [8]:

$$\hat{\mathbf{\Pi}}_n = \hat{\mathbf{U}}_n \hat{\mathbf{U}}_n^H. \quad (5)$$

The basic idea behind the planewave MUSIC algorithm is that the reciprocal of the “distance” between the estimated noise subspace and the true noise subspace has sharp peaks around the DOAs. Thus, if one plots this quantity versus all possible angles, estimates of DOAs can be determined by the maxima of the angular spectrum. The spatial spectrum of the MUSIC algorithm is given by [8]:

$$P_{MUSIC}(\theta) = \frac{\mathbf{a}(\theta)^H \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \hat{\mathbf{\Pi}}_n \mathbf{a}(\theta)} \quad (6)$$

where $\mathbf{a}(\theta) = [1 \ e^{-j\beta d \cos \theta} \ e^{-j2\beta d \cos \theta} \ \dots \ e^{-j(N-1)\beta d \cos \theta}]^T$ is the direction vector that accounts for a plane wave impinging on the array, β is the wave number in the medium of propagation, and d is the distance between two receivers.

It is important to realize that the formulation of the array processing problem presented in this section implicitly assumes that the radiator is infinitely distant so that the scattered field has planar wavefronts at the sensor array. Thus, the elements of the direction vector $\mathbf{a}(\theta)$ are complex exponentials indicative of plane wave signals. However in many applications, including GPR, the receivers are in the near-field region of the radiating sources, resulting in non-planar wavefronts. The target localization problem, therefore, not only requires the DOA relative to the array but also the range of the target from a point on the array. The MUSIC-based MFP described in the next section supplements the plane wave MUSIC to address the near field localization.

3. MATCHED FIELD PROCESSING

As mentioned in the introduction, the matched field processing [10] uses the spatial complexities of the fields to localize sources in underwater acoustics. In a similar manner, plane wave MUSIC outlined in Section 2 can be modified so that the direction vector is filled with the type of the wavefront impinging on the array. As a result, the problem of non-planar wavefronts caused by near field scattering is resolved, and both the range and angle of the scatterer can be estimated. Therefore, MUSIC-based MFP forms the following spectrum:

$$P_{MUSIC}(r, \theta) = \frac{\mathbf{a}(r, \theta)^H \mathbf{a}(r, \theta)}{\mathbf{a}(r, \theta)^H \hat{\mathbf{\Pi}}_n \mathbf{a}(r, \theta)} \quad (7)$$

where the direction vector $\mathbf{a}(r, \theta)$ is now filled with the type of wavefront expected to impinge on the receiver array. For example, if one is concerned with the localization of independent point sources in the near field of the array, spherical MUSIC [12] can be employed to find both the DOAs and the distance of the object from the array. Spherical MUSIC uses $e^{-j\beta r_{mn}}/r_{mn}$ to fill in the direction vector, as opposed to plane wave MUSIC which uses $e^{-j\beta r_n \cos \theta_m}$, where r_{mn} is the distance between the n th array receiver and the m th source (object), r_n is the distance between the origin and the n th receiver, θ_m is the DOA of m th source, and β is the wavenumber in the medium of propagation. Since the detection problem is parameterized by an angle and a distance variable, a two dimensional search in this parameter space is necessary.

For the inverse scattering problem, however, the direction vector $\mathbf{a}(r, \theta)$ is filled with the scattered fields from possible object locations, and the location $(\hat{r}, \hat{\theta})$ maximizing the MUSIC spectrum in (7) is selected as the estimated object center. Because a two dimensional search requires that the exact scattered field be calculated at each point of the parameter mesh, MFP is in general computationally intensive. In the event that the object to be detected is modeled as a simple shape, however, computing the exact scattered field can be relatively simple. In this paper, we simplify the shapes of the objects by replacing them with infinitely long circular cylinders. With simple shapes, the forward scattering problem can easily be solved using harmonic expansions of the fields, see Appendix A for details. In these field calculations, the air-earth interface is ignored in order to simplify the formulation.

To summarize, the MUSIC-based MFP algorithm proceeds as follows:

1. Using the data model in (1), perform L , single-frequency scattering experiments each producing a snapshot vector, \mathbf{y}_l , composed of the observed scattered fields over the receiver array
2. Estimate the autocovariance matrix $\hat{\mathbf{R}}$ using (3)
3. Perform an eigenanalysis on $\hat{\mathbf{R}}$ to find the noise-subspace projector $\hat{\mathbf{\Pi}}_n$ (4) and (5)
4. For each point (r_k, θ_k) on a predefined range and angle grid, fill in the direction vector $\mathbf{a}(r_k, \theta_k)$ with the scattered field due to an object placed in that location, and calculate the associated value of $P_{MUSIC}(r_k, \theta_k)$ in (7)
5. Choose $(\hat{r}, \hat{\theta})$ as the estimate of the target location that grid point with the largest P_{MUSIC} .

Fig. 2(b) shows the MUSIC spectrum when a metallic mine-like object in 7.5 cm diameter is placed 15 cm below the array as depicted in Fig. 2(a). The 33-element linear, uniform receiver array spans an aperture of 1.5 meters. All sensors are assumed to be ideal, isotropic receivers. The operating frequency is 1.0 GHz and the plane wave is incident with 90 degrees. The lossy, homogeneous background has the same electrical characteristics of 5% moist San Antonio clay loam or 10% moist Puerto Rico clay loam ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} \text{ S/m}$) at around 1.0 GHz [15]. The signal to noise ratio (SNR) is fixed at 0 decibels. As Fig. 2(b) depicts, the location of the object ($r = 15\text{cm}$, $\theta = 90^\circ$) is indicated with a very sharp peak. For relatively high SNR values, the peak remains prominent, and the estimation error is usually on the order of grid size. For lower SNR levels, the peak gets flatter, and as a result estimation errors increase.

4. CRAMER-RAO BOUND FOR MATCHED FIELD PROCESSING

The Cramer-Rao Bound (CRB) provides very valuable information about the lower limit for the variance of any unbiased estimator. In order to find CRB, however, one should have a closed form expression of the log-likelihood function. In this section, we will extend the results in [14] to include the previously described problem of object localization in [13]. Since the additive noise in (1) is white, Gaussian distributed, the log-likelihood function can be written as [14]:

$$\ln \mathcal{L} = \text{constant} - 2NL \ln \sigma - \frac{1}{\sigma^2} \sum_{l=1}^L [\mathbf{y} - \mathbf{E}_s(r, \theta)\mathbf{x}]^H [\mathbf{y} - \mathbf{E}_s(r, \theta)\mathbf{x}] \quad (8)$$

(a) Geometry used for MFP Example

(b) Logarithm of MUSIC spectrum given by (7)

Figure 2. MFP localization example: single metallic object in a lossy, homogeneous background

where σ^2 is the noise variance, N is the number of receivers and L is the number of data vectors used for estimating the covariance matrix $\hat{\mathbf{R}}$.

Given the log-likelihood function, the Fisher Information Matrix (FIM) can be written as:

$$J = \begin{bmatrix} \Gamma_{rr} & \Gamma_{r\theta} \\ \Gamma_{\theta r} & \Gamma_{\theta\theta} \end{bmatrix} \quad (9)$$

where $\Gamma_{pq} = E[\frac{\partial^2 \ln \mathcal{L}}{\partial p \partial q}]$, $p = \{r, \theta\}$ and $q = \{r, \theta\}$. Following the same steps as [14], the entries of FIM, can be written as:

$$\Gamma_{pq} = \frac{2}{\sigma^2} \sum_{l=1}^L \text{Re}\{\mathbf{x}^H \mathbf{D}_p^H \mathbf{D}_q \mathbf{x}\}, \quad (10)$$

where $\mathbf{D}_p = \frac{\partial \mathbf{E}_s(r, \theta)}{\partial p}$ and $\mathbf{D}_q = \frac{\partial \mathbf{E}_s(r, \theta)}{\partial q}$ with $p = \{r, \theta\}$ and $q = \{r, \theta\}$. Since \mathbf{x} is constant over L experiments, (10) can be further reduced to:

$$\Gamma_{pq} = 2L \times \text{SNR} \times \text{Re}\{\mathbf{D}_p^H \mathbf{D}_q\} \quad (11)$$

where SNR is defined as $\frac{|x|^2}{\sigma^2}$. The CRB matrix for r and θ , then, can be expressed in terms of FIM entries as:

$$\text{CRB}(r, \theta) = \begin{bmatrix} \text{crb}_{rr} & \text{crb}_{r\theta} \\ \text{crb}_{\theta r} & \text{crb}_{\theta\theta} \end{bmatrix} = \begin{bmatrix} \Gamma_{rr} & \Gamma_{r\theta} \\ \Gamma_{\theta r} & \Gamma_{\theta\theta} \end{bmatrix}^{-1} \quad (12)$$

Finally, inserting (11) into (12), we obtain:

$$\text{CRB}(r, \theta) = \frac{1}{2L \times \text{SNR}} \left\{ \text{Re} \begin{bmatrix} \mathbf{D}_r^H \mathbf{D}_r & \mathbf{D}_r^H \mathbf{D}_\theta \\ \mathbf{D}_\theta^H \mathbf{D}_r & \mathbf{D}_\theta^H \mathbf{D}_\theta \end{bmatrix} \right\}^{-1}. \quad (13)$$

In the rest of the paper, we will refer crb_{rr} and $\text{crb}_{\theta\theta}$ as the Cramer-Rao Bounds of radial and azimuthal coordinate variables, respectively. The proper interpretation of CRB matrix is that if \hat{r} and $\hat{\theta}$ are unbiased estimates of polar variables r and θ , then

$$\begin{bmatrix} E\{(\hat{r} - r)^2\} & E\{(\hat{r} - r)(\hat{\theta} - \theta)\} \\ E\{(\hat{\theta} - \theta)(\hat{r} - r)\} & E\{(\hat{\theta} - \theta)^2\} \end{bmatrix} - \text{CRB}(r, \theta) \quad (14)$$

is positive semi-definite [16].

5. EXAMPLES

In this section we numerically evaluate the CRB derived in previous section for the geometry depicted in Fig. 2(a). The object to be localized is a metallic mine-like scatterer modeled as an infinitely long circular cylinder, with 7.5 cm diameter in cross-section. The object is placed 15 cm beneath a 33-element receiver array which spans an aperture of 1.5 meters. Center of the array is used as the origin of polar coordinate system that defines the object's radial and azimuthal coordinates. All sensors are assumed to be ideal, isotropic receivers, and form a linear, uniform receiver array. The operating frequency is 1.0 GHz and the plane wave is incident with 90 degrees. The calculation of scattered electromagnetic field and its derivatives is further simplified by ignoring the air-earth interface. The lossy, homogeneous background has the same electrical characteristics of 5% moist San Antonio clay loam or 10% moist Puerto Rico clay loam ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} \text{ S/m}$) at around 1.0 GHz [15]. The signal to noise ratio (SNR) is defined as $\frac{|x|^2}{\sigma^2}$, with $x = 1$, see the discussion in Section 2. In all examples, the data model (1) is generated $L = 250$ times to obtain the sample covariance matrix $\hat{\mathbf{R}}$ using (3).

We present several examples in this section: the first one is the evaluation of theoretical CRB given by (13), the second one is a comparison of analytical CRB with Monte-Carlo simulations, and the last one is about the effect of model mismatch on detection performance.

5.1. Evaluation of CRB

In order to determine CRB, one needs to calculate the derivatives of the scattered electric field E_s with respect to radial coordinate r and azimuthal coordinate θ . Finding these derivatives for single object is quite straightforward but tedious, the reader is referred to Appendix A for details of determining fields and their derivatives.

Fig. 3 depicts the dependence of CRB on inter-element spacing for the localization geometry given in Fig. 2(a). Here, the number of receivers is $N = 33$, and the length of array aperture is varied from 10 cm to 2 meters. For each array length, the object is placed under the center of the array. SNR is 0 decibels. Fig. 3(a) shows the variance of estimated radial coordinate \hat{r} , and Fig. 3(b) shows that for estimated azimuthal coordinate $\hat{\theta}$. Axes corresponding to inter-element spacing are normalized to the wavelength in the medium of propagation. It is interesting to note that these curves reach minimum for different inter-element spacings. This observation suggests that if one wants to minimize the variance of \hat{r} , there exists an estimator which approaches this minimum variance for a certain value of inter-element spacing, and this value is distinctly different from the one that minimizes the variance of $\hat{\theta}$. Fig. 3 also reveals that in order to achieve the minimum point on CRB curves both for \hat{r} and $\hat{\theta}$, inter-element spacing should be much smaller than the half-wavelength criterion suggested by the sampling theorem.

(b) Variance of $\hat{\theta}$

Figure 3. Analytical CRB *vs.* inter-element spacing

(a) Variance of \hat{r}

(b) Variance of $\hat{\theta}$

Figure 4. Comparison of analytical CRB with sample variances of MUSIC-MFP and ML-MFP

5.2. Comparison of CRB with Monte-Carlo Simulations

In this example Monte-Carlo simulated sample variances are compared with the analytical CRB given in (13). We have run the MFP algorithm defined in Section 3 for the geometry given in Fig. 2(a) 1000 times, each time obtaining an estimate of radial (\hat{r}) and azimuthal ($\hat{\theta}$) coordinates of the object. At the end,

sample variances of \hat{r} and $\hat{\theta}$ are calculated and compared with the CRB variances crb_{rr} and $\text{crb}_{\theta\theta}$ obtained analytically. Fig. 4 shows the comparison of variance of estimates obtained using MUSIC-MFP (circles) against the CRB (solid line). As expected, increasing signal to noise ratios results in decreasing variances. In addition, we compared the performance of MUSIC-MFP, and CRB with the maximum likelihood (ML) estimator. For this purpose, MFP is carried out by replacing MUSIC spectrum of (7) with ML cost [14] in the algorithm:

$$F(r, \theta) = \text{tr}\{[I - \mathbf{E}_s(r, \theta)(\mathbf{E}_s^H(r, \theta)\mathbf{E}_s(r, \theta))^{-1}\mathbf{E}_s^H(r, \theta)]\hat{\mathbf{R}}\} \quad (15)$$

where tr denotes the sum of diagonal entries. By minimizing $F(r, \theta)$, maximum likelihood estimates ($\hat{r}_{ML}, \hat{\theta}_{ML}$) of r and θ can be found. In Fig. 4, diamonds denote the variances of these quantities obtained with 1000 Monte-Carlo runs of ML-MFP. As these figures depict, ML-MFP performs better than MUSIC-MFP for low signal to noise ratios, and with increasing SNR both converge to the same value.

Figure 5. Effects of mismatch on estimated object location and estimation variances

5.3. Model Mismatch in Object Radius

As the last example, we consider the model mismatch in the object radius. Understanding the system performance is quite important in model-based detection algorithms. For this purpose we have defined a mismatch factor (MF), such that the MUSIC-MFP searches for an object of radius $\text{MF} \times \rho$, while the actual object is of radius ρ . The system described at the beginning of this section is used in the experiment with the object geometry given by Fig. 2(a). Signal to noise ratio is fixed at 20 decibels. The sample covariance matrix in (3) is evaluated using the scattered field from the object with radius ρ . Then, while estimating \hat{r} and $\hat{\theta}$, the direction vector $\mathbf{a}(r, \theta)$ in (7) is filled with the scattered field from an object whose radius is mismatched, i.e. $\rho_{\text{mismatch}} = \text{MF} \times \rho$. This experiment is repeated 500 times, and sample mean and variances of \hat{r} and $\hat{\theta}$ are plotted in Fig. 5. Part (a) of this figure depicts the sample mean of \hat{r} . It is interesting to note that, as the mismatch factor increases, MUSIC-MFP localizes the object with increasing bias. Therefore, for this example model mismatch causes bias in the radial coordinate's estimate. Even though not plotted here, sample mean of $\hat{\theta}$ is insensitive to the mismatch factor. This would be expected

since the changes in radius does not alter the symmetry around the center of the object, thus azimuthal coordinate's estimate is not affected. Fig. 5(b) shows that the variance of $\hat{\theta}$ decreases with increasing radius. This is expected given the plot in Fig. 5(a), since MUSIC-MFP thinks that an object of radius $MF \times \rho$ is buried at a depth different from the true depth. The variance of \hat{r} , on the other hand, remains almost constant over all mismatch factors.

6. CONCLUSIONS

In this paper, performance bounds for detection of objects using the matched field processing is derived and analytical results are verified with simulations. The object geometry is simplified with infinitely long circular cylinders embedded in a homogeneous background whose electrical characteristics are known. The uniform, linear array with ideal, isotropic sensors is used as the receiver array while the medium is illuminated by a plane wave.

In previous work [13], we have demonstrated that it is possible to use the matched field processing (MFP) to detect and localize mine and drum sized objects for various background and SNR scenarios. Here, we have derived analytical expressions of the performance bounds on estimates of object coordinates. The performance bounds basically indicate the best case scenario with the best estimator. Therefore, with these bounds available, it is possible to know if an object can be located with specified accuracy. Analysis of theoretical bounds have revealed that there exists an optimum inter-element spacing for which the bound is minimum. Thus, if an estimator is known to be bounded by CRB tightly, choosing the optimum inter-element spacing would minimize the estimation error. The analytical performance bounds are, then, verified with two simulation schemes: MUSIC based MFP, and ML based MFP. Simulations have verified that sample variances always lie above the values established by CRB. It has been observed that the difference between variances of estimates of object coordinates and their respective lower bounds gets smaller as the signal to noise ratio increases. Finally, it is shown that model mismatch in the object radius causes bias in estimating the object's radial coordinate. Furthermore, it is observed that if the object radius in the model is larger(smaller) than the true radius, variance of sample azimuthal coordinate $\hat{\theta}$ is smaller(larger).

As for the future work, we would like to extend present results in three directions. In the theoretical performance bound area, we will derive analytical expressions for the variances of estimation errors in MUSIC-MFP and extend the results of CRB analysis for multiple objects. In terms of simulations, we will run Monte-Carlo experiments to observe the change in error variances as the object location under the receiver array changes. For the model mismatch issue, we will extend the analysis to include mismatches in electrical properties of background and object. In order to account for mismatches due to object shapes, we would also like to analyze shape mismatch where the model and true object shapes are different.

APPENDIX A.

The scattered electromagnetic field from a cylindrical object with circular cross-section due to a plane wave incidence can be calculated using the harmonic expansions of the fields [17]. Given the center of the object (x_0, y_0) and incidence angle of the planewave ϕ_{inc} , the scattered field at the i th receiver location $\mathbf{r}_i = (r_i, \phi_i)$ in the coordinate system of object (Fig. 6) is given by:

$$E_s(\mathbf{r}_i) = \sum_{m=-\infty}^{\infty} j^{-m} c_m H_m^{(2)}(\beta r_i) e^{jm(\phi_i + \pi - \phi_{inc})} \quad (16)$$

where

$$c_m = -\frac{J_m(\beta \rho)}{H_m^{(2)}(\beta \rho)}$$

for metallic scatterers. The radius of the object is ρ and the wavenumber in the medium of propagation is β . The coefficients c_m decay quite rapidly as the number of harmonics increases. Thus, infinite sum in (16) can be truncated at M . The value of M is proportional to the radius of the object, $M \propto \beta\rho$. The variable M representing the number of harmonics here should not be confused with the same variable representing the dimension of the signal subspace in the body of the paper. It should be noted that the origin of coordinate system while calculating (16) is the center of the object, and coordinates of all sensors should be translated[†] to the object's coordinate system in polar form. Therefore, for every object location, this translation has to be carried out repeatedly.

Figure 6. Geometry for calculation of the scattered field and its derivatives

The derivatives with respect to object's polar coordinates (r, θ) have to be taken carefully, since we have to translate coordinates of receivers into object's local coordinate system, and then calculate the scattered field in that coordinate system. Therefore, we use the definition of the derivative operation to find the derivatives of the fields:

$$\frac{\partial \mathbf{E}_s(r, \theta)}{\partial r} = \lim_{\Delta r \rightarrow 0} \frac{\mathbf{E}_s(r + \Delta r, \theta) - \mathbf{E}_s(r, \theta)}{\Delta r} \quad (17)$$

and

$$\frac{\partial \mathbf{E}_s(r, \theta)}{\partial \theta} = \lim_{\Delta \theta \rightarrow 0} \frac{\mathbf{E}_s(r, \theta + \Delta \theta) - \mathbf{E}_s(r, \theta)}{\Delta \theta}. \quad (18)$$

Here $\mathbf{E}_s(r, \theta) = [E_s(\mathbf{r}_1), E_s(\mathbf{r}_2), \dots, E_s(\mathbf{r}_N)]^T$, where N is the number of sensors in the array. To find $\mathbf{E}_s(r + \Delta r, \theta)$ and $\mathbf{E}_s(r, \theta + \Delta \theta)$, the center of the object should be expressed in terms of its original center (x_0, y_0) when it is moved by an infinitesimal amount in r and θ direction. When the object is moved in r -direction by Δr , the new center (x_r, y_r) becomes:

$$x_r = x_0 + \Delta r \cos(\mu) \quad y_r = y_0 - \Delta r \sin(\mu).$$

[†]Translation of coordinates between two points is straightforward and is not discussed here

The angle μ can be expressed in terms of θ . When the object is moved in θ -direction by $\Delta\theta$, the new center (x_θ, y_θ) becomes:

$$x_\theta = x_0 - r\Delta\theta \cos(\psi) \quad y_\theta = y_0 - r\Delta\theta \sin(\psi)$$

where ψ can be expressed in terms of θ and $\Delta\theta$. Once the new object centers are found, all receiver coordinates can be translated to the new object centers where the scattered field is calculated. Having obtained $\mathbf{E}_s(r + \Delta r, \theta)$ and $\mathbf{E}_s(r, \theta + \Delta\theta)$, the derivatives of the scattered fields with respect to r and θ can be determined using (17) and (18), respectively.

ABSTRACT

In recent years there has been considerable interest in the use of ground penetrating radar (GPR) for the non-invasive detection and localization of buried objects. In a previous work, we have considered the use of high resolution array processing methods for solving these problems for measurement geometries in which an array of electromagnetic receivers observes the fields scattered by the subsurface targets in response to a plane wave illumination. Our approach uses the MUSIC algorithm in a matched field processing (MFP) scheme to determine both the range and the bearing of the objects.

In this paper we derive the Cramer-Rao bounds (CRB) for this MUSIC-based approach analytically. Analysis of the theoretical CRB has shown that there exists an optimum inter-element spacing of array elements for which the CRB is minimum. Furthermore, the optimum inter-element spacing minimizing CRB is smaller than the conventional half wavelength criterion. The theoretical bounds are then verified for two estimators using Monte-Carlo simulations. The first estimator is the MUSIC-based MFP and the second one is the maximum likelihood based MFP. The two approaches differ in the cost functions they optimize. We observe that Monte-Carlo simulated error variances always lie above the values established by CRB. Finally, we evaluate the performance of our MUSIC-based algorithm in the presence of model mismatches. Since the detection algorithm strongly depends on the model used, we have tested the performance of the algorithm when the object radius used in the model is different from the true radius. This analysis reveals that the algorithm is still capable of localizing the objects with a bias depending on the degree of mismatch.

1. INTRODUCTION

Non-invasive detection and localization of buried objects using ground penetrating radar (GPR) type geometries have been of interest to many researchers in recent years. Some of the most promising application areas for this technology include mine detection and hazardous waste remediation.

In subsurface object detection most often a pixel-by-pixel map of the region of interest is produced and the detection is then made by post-processing the image [1–3]. However, since this inverse problem is inherently ill-posed, the image-then-detect approach is quite sensitive to noise. While the ill-posedness can be off-set through regularization [4], typical regularization methods result in smooth images thereby making the detection all the more difficult. On the other hand, making use of the fact that the ultimate goal of the problem is the localization of objects with known structures, we can reparameterize the problem within an object-based detection framework [5–7]. Rather than looking for a large number of pixels, we extract the information about a small number of unknowns from the data: specifically the coordinates of the buried objects. By constraining the degrees of freedom in this manner, ill-posedness is substantially reduced and the resulting algorithms prove to be robust to noise.

The inherent array structure of GPR measurement geometry in Fig. 1 suggests that the high resolution array processing techniques [8], in particular, multiple signal classification (MUSIC) algorithm [9], quite popular in the signal processing community would be well suited for the subsurface detection problem. However, direction finding array processing techniques assume that the sources are infinitely far away so that the waveform received on the array is planar. For subsurface object detection case, on the other hand, the objects are located relatively closer to the receiver array, thus the scattered field from these objects across the array is not planar. In addition, for such near field objects, range as well as the direction of arrival has to be determined in order to localize the object. In ocean acoustics, the matched field processing (MFP) [10] has been successfully used for localization of sources modeled as point radiators. MFP is an array processing technique that uses the spatial complexities of the fields to localize sources, and thus allows for estimation of both the range and the bearing of the objects. Recently, MFP has been adapted to other application areas such as stratospherical electromagnetics [11], acoustics [12], and subsurface object detection [13]. In [13], we have demonstrated that MUSIC-based MFP can be used to detect and localize simple shaped metallic and dielectric objects over a wide range of soil characteristics and signal to noise ratios quite accurately.

In this paper, we extend the results of [13] to include the performance analysis for the matched field processing. Since we use a model based approach, it is imperative to know the performance of the algorithm against changes in problem parameters. For this purpose, we derive the Cramer-Rao performance bound for an unbiased estimator of the object position similar to derivations in [14]. Analytical bounds of range and bearing variables are then validated by running Monte-Carlo experiments for two estimators. The first one is MUSIC-based MFP described in [13], and the second one is the maximum likelihood (ML) based MFP. We observe that asymptotically MUSIC and ML estimators perform very similarly as reported in [14]. In addition, plotting the analytical CRB against the array length with fixed number of receivers reveals that there are optimal array lengths for estimating the range and bearing of an object, which minimizes the lower bound. Therefore, if one aims to determine the target's range or bearing with minimum variance, there exists an optimal array length, corresponding to an optimal inter-element spacing. Finally, we show the sensitivity of model mismatch on object radius by using a different radius in MFP model than the true radius of the object. This analysis demonstrates that under model mismatches, MFP can still localize the objects with a bias dependent on the degree of mismatch.

The remainder of the paper is organized as follows. In Section 2, we introduce the problem geometry, and brief overview of plane wave MUSIC. In Section 3, we review the matched field processing for subsurface

Figure 1. Problem geometry

detection problems. The Cramer-Rao lower bound for MFP is derived in Section 4. Numerical examples are presented in Section 5, and in Section 6, conclusions will be drawn and future directions will be presented.

2. PROBLEM GEOMETRY AND BACKGROUND

The ground penetrating radar (GPR) type measurement scheme depicted in Fig. 1, is considered in this paper. The objects are buried in a background for which the constant electrical characteristics (relative permittivity and conductivity) are assumed known. A transverse magnetic (TM) polarized plane wave, $E_i(\mathbf{r})$, impinges on the objects, inducing surface and volume currents which in turn radiate a scattered field, $E_s(\mathbf{r})^\dagger$. An important assumption in our approach is that the material properties and the shapes of the objects are known a priori. The scattered electric field from these objects is spatially sampled by a uniformly spaced, linear array with isotropic receiver characteristics. The measured data at the sensor outputs are:

$$\mathbf{y} = \mathbf{E}_s \mathbf{x} + \mathbf{n}, \quad (1)$$

where $\mathbf{E}_s = [E_s(\mathbf{r}_1) \ E_s(\mathbf{r}_2) \ \cdots E_s(\mathbf{r}_N)]^T$, \mathbf{r}_i , $i = 1, 2, \dots, N$, is the vector from the origin to the i th receiver location and \mathbf{n} is spatially and temporally white Gaussian noise. If M objects scatter the incident field, then \mathbf{E}_s becomes an $N \times M$ matrix with each column formed by the scattered field due to a different object. For time domain applications, the vector \mathbf{x} contains the time variations. Since we do our analysis in the frequency domain, and suppress $e^{j\omega t}$, $\mathbf{x} = 1$ for multiple scatterers, and $x = 1$ for single object. For the sake of simplicity, this paper deals with the case where there is only one scatterer in the region of interest. Thus, the data model can simply be written as:

$$\mathbf{y} = \mathbf{E}_s + \mathbf{n}. \quad (2)$$

The structure of the receivers in Fig. 1 coupled with the underlying problem of target detection suggests the use of array processing methods for localizing buried targets. In this paper we consider the MUSIC (Multiple Signal Classification) [9] algorithm. Traditionally, MUSIC and other direction finding techniques

[†]All analysis is in frequency domain, thus the $e^{j\omega t}$ time dependence will be dropped.

are used to determine the directions of arrival (DOA) of plane waves to a receiver array. In the rest of this section, we will briefly review the plane wave MUSIC.

The experiment as represented by the data model in (1) is repeated many times in order to determine the statistics of \mathbf{y} . In particular, if L experiments are performed, then the maximum likelihood estimate of the spatial autocovariance matrix $\mathbf{R} = E\{\mathbf{y}\mathbf{y}^H\}$ is given by:

$$\hat{\mathbf{R}} = \frac{1}{L} \sum_{l=1}^L \mathbf{y}_l \mathbf{y}_l^H \quad (3)$$

where \mathbf{y}_l is the data measured at the l th experiment, and superscript H denotes conjugate transpose. The sample covariance matrix $\hat{\mathbf{R}}$ is used in MUSIC algorithm to separate signal and noise subspaces through the eigenspace decomposition [8]:

$$\hat{\mathbf{R}} = \hat{\mathbf{U}}_s \hat{\mathbf{\Lambda}}_s \hat{\mathbf{U}}_s^H + \hat{\mathbf{U}}_n [\hat{\sigma}^2 \mathbf{I}] \hat{\mathbf{U}}_n^H \quad (4)$$

where $\hat{\mathbf{U}}_s$ is the estimated signal subspace matrix and contains the M signal eigenvectors, and $\hat{\mathbf{U}}_n$ is the estimated noise subspace matrix and contains $N - M$ noise eigenvectors of multiple noise eigenvalue $\hat{\sigma}^2$. The projection operator onto the noise subspace is defined as [8]:

$$\hat{\mathbf{\Pi}}_n = \hat{\mathbf{U}}_n \hat{\mathbf{U}}_n^H. \quad (5)$$

The basic idea behind the planewave MUSIC algorithm is that the reciprocal of the “distance” between the estimated noise subspace and the true noise subspace has sharp peaks around the DOAs. Thus, if one plots this quantity versus all possible angles, estimates of DOAs can be determined by the maxima of the angular spectrum. The spatial spectrum of the MUSIC algorithm is given by [8]:

$$P_{MUSIC}(\theta) = \frac{\mathbf{a}(\theta)^H \mathbf{a}(\theta)}{\mathbf{a}(\theta)^H \hat{\mathbf{\Pi}}_n \mathbf{a}(\theta)} \quad (6)$$

where $\mathbf{a}(\theta) = [1 \ e^{-j\beta d \cos \theta} \ e^{-j2\beta d \cos \theta} \ \dots \ e^{-j(N-1)\beta d \cos \theta}]^T$ is the direction vector that accounts for a plane wave impinging on the array, β is the wave number in the medium of propagation, and d is the distance between two receivers.

It is important to realize that the formulation of the array processing problem presented in this section implicitly assumes that the radiator is infinitely distant so that the scattered field has planar wavefronts at the sensor array. Thus, the elements of the direction vector $\mathbf{a}(\theta)$ are complex exponentials indicative of plane wave signals. However in many applications, including GPR, the receivers are in the near-field region of the radiating sources, resulting in non-planar wavefronts. The target localization problem, therefore, not only requires the DOA relative to the array but also the range of the target from a point on the array. The MUSIC-based MFP described in the next section supplements the plane wave MUSIC to address the near field localization.

3. MATCHED FIELD PROCESSING

As mentioned in the introduction, the matched field processing [10] uses the spatial complexities of the fields to localize sources in underwater acoustics. In a similar manner, plane wave MUSIC outlined in Section 2 can be modified so that the direction vector is filled with the type of the wavefront impinging on the array. As a result, the problem of non-planar wavefronts caused by near field scattering is resolved, and both the range and angle of the scatterer can be estimated. Therefore, MUSIC-based MFP forms the following spectrum:

$$P_{MUSIC}(r, \theta) = \frac{\mathbf{a}(r, \theta)^H \mathbf{a}(r, \theta)}{\mathbf{a}(r, \theta)^H \hat{\mathbf{\Pi}}_n \mathbf{a}(r, \theta)} \quad (7)$$

where the direction vector $\mathbf{a}(r, \theta)$ is now filled with the type of wavefront expected to impinge on the receiver array. For example, if one is concerned with the localization of independent point sources in the near field of the array, spherical MUSIC [12] can be employed to find both the DOAs and the distance of the object from the array. Spherical MUSIC uses $e^{-j\beta r_{mn}}/r_{mn}$ to fill in the direction vector, as opposed to plane wave MUSIC which uses $e^{-j\beta r_n \cos \theta_m}$, where r_{mn} is the distance between the n th array receiver and the m th source (object), r_n is the distance between the origin and the n th receiver, θ_m is the DOA of m th source, and β is the wavenumber in the medium of propagation. Since the detection problem is parameterized by an angle and a distance variable, a two dimensional search in this parameter space is necessary.

For the inverse scattering problem, however, the direction vector $\mathbf{a}(r, \theta)$ is filled with the scattered fields from possible object locations, and the location $(\hat{r}, \hat{\theta})$ maximizing the MUSIC spectrum in (7) is selected as the estimated object center. Because a two dimensional search requires that the exact scattered field be calculated at each point of the parameter mesh, MFP is in general computationally intensive. In the event that the object to be detected is modeled as a simple shape, however, computing the exact scattered field can be relatively simple. In this paper, we simplify the shapes of the objects by replacing them with infinitely long circular cylinders. With simple shapes, the forward scattering problem can easily be solved using harmonic expansions of the fields, see Appendix A for details. In these field calculations, the air-earth interface is ignored in order to simplify the formulation.

To summarize, the MUSIC-based MFP algorithm proceeds as follows:

1. Using the data model in (1), perform L , single-frequency scattering experiments each producing a snapshot vector, \mathbf{y}_l , composed of the observed scattered fields over the receiver array
2. Estimate the autocovariance matrix $\hat{\mathbf{R}}$ using (3)
3. Perform an eigenanalysis on $\hat{\mathbf{R}}$ to find the noise-subspace projector $\hat{\mathbf{\Pi}}_n$ (4) and (5)
4. For each point (r_k, θ_k) on a predefined range and angle grid, fill in the direction vector $\mathbf{a}(r_k, \theta_k)$ with the scattered field due to an object placed in that location, and calculate the associated value of $P_{MUSIC}(r_k, \theta_k)$ in (7)
5. Choose $(\hat{r}, \hat{\theta})$ as the estimate of the target location that grid point with the largest P_{MUSIC} .

Fig. 2(b) shows the MUSIC spectrum when a metallic mine-like object in 7.5 cm diameter is placed 15 cm below the array as depicted in Fig. 2(a). The 33-element linear, uniform receiver array spans an aperture of 1.5 meters. All sensors are assumed to be ideal, isotropic receivers. The operating frequency is 1.0 GHz and the plane wave is incident with 90 degrees. The lossy, homogeneous background has the same electrical characteristics of 5% moist San Antonio clay loam or 10% moist Puerto Rico clay loam ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} \text{ S/m}$) at around 1.0 GHz [15]. The signal to noise ratio (SNR) is fixed at 0 decibels. As Fig. 2(b) depicts, the location of the object ($r = 15\text{cm}$, $\theta = 90^\circ$) is indicated with a very sharp peak. For relatively high SNR values, the peak remains prominent, and the estimation error is usually on the order of grid size. For lower SNR levels, the peak gets flatter, and as a result estimation errors increase.

4. CRAMER-RAO BOUND FOR MATCHED FIELD PROCESSING

The Cramer-Rao Bound (CRB) provides very valuable information about the lower limit for the variance of any unbiased estimator. In order to find CRB, however, one should have a closed form expression of the log-likelihood function. In this section, we will extend the results in [14] to include the previously described problem of object localization in [13]. Since the additive noise in (1) is white, Gaussian distributed, the log-likelihood function can be written as [14]:

$$\ln \mathcal{L} = \text{constant} - 2NL \ln \sigma - \frac{1}{\sigma^2} \sum_{l=1}^L [\mathbf{y} - \mathbf{E}_s(r, \theta)\mathbf{x}]^H [\mathbf{y} - \mathbf{E}_s(r, \theta)\mathbf{x}] \quad (8)$$

(a) Geometry used for MFP Example

(b) Logarithm of MUSIC spectrum given by (7)

Figure 2. MFP localization example: single metallic object in a lossy, homogeneous background

where σ^2 is the noise variance, N is the number of receivers and L is the number of data vectors used for estimating the covariance matrix $\hat{\mathbf{R}}$.

Given the log-likelihood function, the Fisher Information Matrix (FIM) can be written as:

$$\mathbf{J} = \begin{bmatrix} \Gamma_{rr} & \Gamma_{r\theta} \\ \Gamma_{\theta r} & \Gamma_{\theta\theta} \end{bmatrix} \quad (9)$$

where $\Gamma_{pq} = E[\frac{\partial^2 \ln \mathcal{L}}{\partial p \partial q}]$, $p = \{r, \theta\}$ and $q = \{r, \theta\}$. Following the same steps as [14], the entries of FIM, can be written as:

$$\Gamma_{pq} = \frac{2}{\sigma^2} \sum_{l=1}^L \text{Re}\{\mathbf{x}^H \mathbf{D}_p^H \mathbf{D}_q \mathbf{x}\}, \quad (10)$$

where $\mathbf{D}_p = \frac{\partial \mathbf{E}_s(r, \theta)}{\partial p}$ and $\mathbf{D}_q = \frac{\partial \mathbf{E}_s(r, \theta)}{\partial q}$ with $p = \{r, \theta\}$ and $q = \{r, \theta\}$. Since \mathbf{x} is constant over L experiments, (10) can be further reduced to:

$$\Gamma_{pq} = 2L \times \text{SNR} \times \text{Re}\{\mathbf{D}_p^H \mathbf{D}_q\} \quad (11)$$

where SNR is defined as $\frac{|x|^2}{\sigma^2}$. The CRB matrix for r and θ , then, can be expressed in terms of FIM entries as:

$$\text{CRB}(r, \theta) = \begin{bmatrix} \text{crb}_{rr} & \text{crb}_{r\theta} \\ \text{crb}_{\theta r} & \text{crb}_{\theta\theta} \end{bmatrix} = \begin{bmatrix} \Gamma_{rr} & \Gamma_{r\theta} \\ \Gamma_{\theta r} & \Gamma_{\theta\theta} \end{bmatrix}^{-1} \quad (12)$$

Finally, inserting (11) into (12), we obtain:

$$\text{CRB}(r, \theta) = \frac{1}{2L \times \text{SNR}} \left\{ \text{Re} \begin{bmatrix} \mathbf{D}_r^H \mathbf{D}_r & \mathbf{D}_r^H \mathbf{D}_\theta \\ \mathbf{D}_\theta^H \mathbf{D}_r & \mathbf{D}_\theta^H \mathbf{D}_\theta \end{bmatrix} \right\}^{-1}. \quad (13)$$

In the rest of the paper, we will refer crb_{rr} and $\text{crb}_{\theta\theta}$ as the Cramer-Rao Bounds of radial and azimuthal coordinate variables, respectively. The proper interpretation of CRB matrix is that if \hat{r} and $\hat{\theta}$ are unbiased estimates of polar variables r and θ , then

$$\begin{bmatrix} E\{(\hat{r} - r)^2\} & E\{(\hat{r} - r)(\hat{\theta} - \theta)\} \\ E\{(\hat{\theta} - \theta)(\hat{r} - r)\} & E\{(\hat{\theta} - \theta)^2\} \end{bmatrix} - \text{CRB}(r, \theta) \quad (14)$$

is positive semi-definite [16].

5. EXAMPLES

In this section we numerically evaluate the CRB derived in previous section for the geometry depicted in Fig. 2(a). The object to be localized is a metallic mine-like scatterer modeled as an infinitely long circular cylinder, with 7.5 cm diameter in cross-section. The object is placed 15 cm beneath a 33-element receiver array which spans an aperture of 1.5 meters. Center of the array is used as the origin of polar coordinate system that defines the object's radial and azimuthal coordinates. All sensors are assumed to be ideal, isotropic receivers, and form a linear, uniform receiver array. The operating frequency is 1.0 GHz and the plane wave is incident with 90 degrees. The calculation of scattered electromagnetic field and its derivatives is further simplified by ignoring the air-earth interface. The lossy, homogeneous background has the same electrical characteristics of 5% moist San Antonio clay loam or 10% moist Puerto Rico clay loam ($\epsilon_b = 6\epsilon_0$, $\sigma_b = 5 \times 10^{-2} \text{ S/m}$) at around 1.0 GHz [15]. The signal to noise ratio (SNR) is defined as $\frac{|x|^2}{\sigma^2}$, with $x = 1$, see the discussion in Section 2. In all examples, the data model (1) is generated $L = 250$ times to obtain the sample covariance matrix $\hat{\mathbf{R}}$ using (3).

We present several examples in this section: the first one is the evaluation of theoretical CRB given by (13), the second one is a comparison of analytical CRB with Monte-Carlo simulations, and the last one is about the effect of model mismatch on detection performance.

5.1. Evaluation of CRB

In order to determine CRB, one needs to calculate the derivatives of the scattered electric field E_s with respect to radial coordinate r and azimuthal coordinate θ . Finding these derivatives for single object is quite straightforward but tedious, the reader is referred to Appendix A for details of determining fields and their derivatives.

Fig. 3 depicts the dependence of CRB on inter-element spacing for the localization geometry given in Fig. 2(a). Here, the number of receivers is $N = 33$, and the length of array aperture is varied from 10 cm to 2 meters. For each array length, the object is placed under the center of the array. SNR is 0 decibels. Fig. 3(a) shows the variance of estimated radial coordinate \hat{r} , and Fig. 3(b) shows that for estimated azimuthal coordinate $\hat{\theta}$. Axes corresponding to inter-element spacing are normalized to the wavelength in the medium of propagation. It is interesting to note that these curves reach minimum for different inter-element spacings. This observation suggests that if one wants to minimize the variance of \hat{r} , there exists an estimator which approaches this minimum variance for a certain value of inter-element spacing, and this value is distinctly different from the one that minimizes the variance of $\hat{\theta}$. Fig. 3 also reveals that in order to achieve the minimum point on CRB curves both for \hat{r} and $\hat{\theta}$, inter-element spacing should be much smaller than the half-wavelength criterion suggested by the sampling theorem.

(a) Variance of \hat{r}

(b) Variance of $\hat{\theta}$

Figure 4. Comparison of analytical CRB with sample variances of MUSIC-MFP and ML-MFP

5.2. Comparison of CRB with Monte-Carlo Simulations

In this example Monte-Carlo simulated sample variances are compared with the analytical CRB given in (13). We have run the MFP algorithm defined in Section 3 for the geometry given in Fig. 2(a) 1000 times, each time obtaining an estimate of radial (\hat{r}) and azimuthal ($\hat{\theta}$) coordinates of the object. At the end,

sample variances of \hat{r} and $\hat{\theta}$ are calculated and compared with the CRB variances crb_{rr} and $\text{crb}_{\theta\theta}$ obtained analytically. Fig. 4 shows the comparison of variance of estimates obtained using MUSIC-MFP (circles) against the CRB (solid line). As expected, increasing signal to noise ratios results in decreasing variances. In addition, we compared the performance of MUSIC-MFP, and CRB with the maximum likelihood (ML) estimator. For this purpose, MFP is carried out by replacing MUSIC spectrum of (7) with ML cost [14] in the algorithm:

$$F(r, \theta) = \text{tr}\{[I - \mathbf{E}_s(r, \theta)(\mathbf{E}_s^H(r, \theta)\mathbf{E}_s(r, \theta))^{-1}\mathbf{E}_s^H(r, \theta)]\hat{\mathbf{R}}\} \quad (15)$$

where tr denotes the sum of diagonal entries. By minimizing $F(r, \theta)$, maximum likelihood estimates ($\hat{r}_{ML}, \hat{\theta}_{ML}$) of r and θ can be found. In Fig. 4, diamonds denote the variances of these quantities obtained with 1000 Monte-Carlo runs of ML-MFP. As these figures depict, ML-MFP performs better than MUSIC-MFP for low signal to noise ratios, and with increasing SNR both converge to the same value.

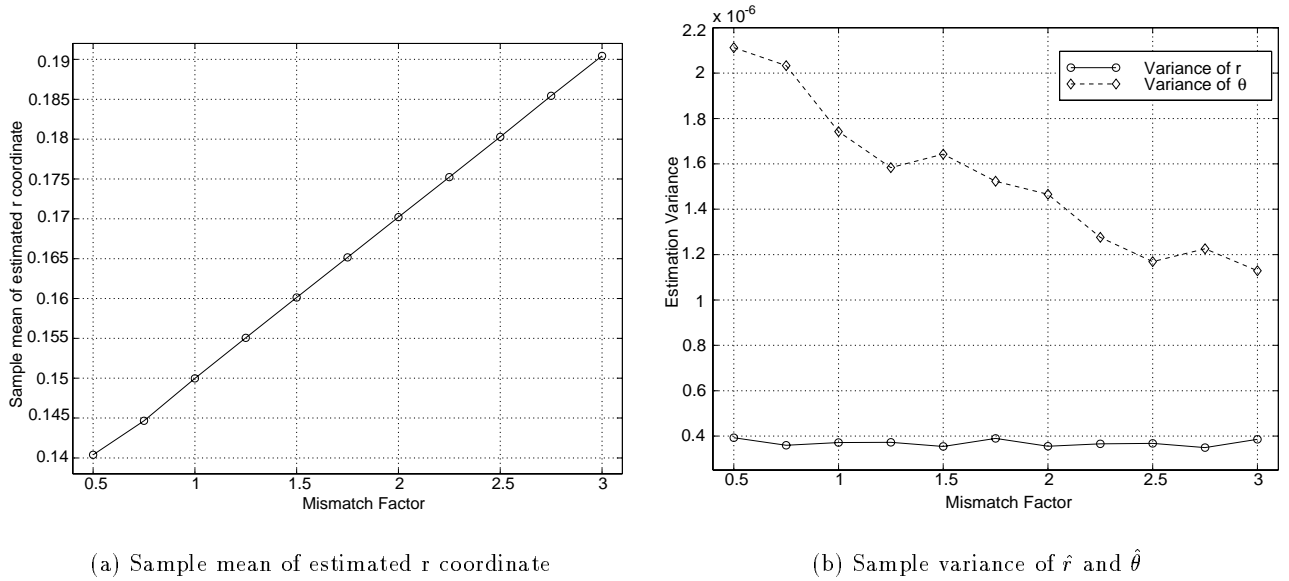

Figure 5. Effects of mismatch on estimated object location and estimation variances

5.3. Model Mismatch in Object Radius

As the last example, we consider the model mismatch in the object radius. Understanding the system performance is quite important in model-based detection algorithms. For this purpose we have defined a mismatch factor (MF), such that the MUSIC-MFP searches for an object of radius $\text{MF} \times \rho$, while the actual object is of radius ρ . The system described at the beginning of this section is used in the experiment with the object geometry given by Fig. 2(a). Signal to noise ratio is fixed at 20 decibels. The sample covariance matrix in (3) is evaluated using the scattered field from the object with radius ρ . Then, while estimating \hat{r} and $\hat{\theta}$, the direction vector $\mathbf{a}(r, \theta)$ in (7) is filled with the scattered field from an object whose radius is mismatched, i.e. $\rho_{\text{mismatch}} = \text{MF} \times \rho$. This experiment is repeated 500 times, and sample mean and variances of \hat{r} and $\hat{\theta}$ are plotted in Fig. 5. Part (a) of this figure depicts the sample mean of \hat{r} . It is interesting to note that, as the mismatch factor increases, MUSIC-MFP localizes the object with increasing bias. Therefore, for this example model mismatch causes bias in the radial coordinate's estimate. Even though not plotted here, sample mean of $\hat{\theta}$ is insensitive to the mismatch factor. This would be expected

since the changes in radius does not alter the symmetry around the center of the object, thus azimuthal coordinate's estimate is not affected. Fig. 5(b) shows that the variance of $\hat{\theta}$ decreases with increasing radius. This is expected given the plot in Fig. 5(a), since MUSIC-MFP thinks that an object of radius $MF \times \rho$ is buried at a depth different from the true depth. The variance of \hat{r} , on the other hand, remains almost constant over all mismatch factors.

6. CONCLUSIONS

In this paper, performance bounds for detection of objects using the matched field processing is derived and analytical results are verified with simulations. The object geometry is simplified with infinitely long circular cylinders embedded in a homogeneous background whose electrical characteristics are known. The uniform, linear array with ideal, isotropic sensors is used as the receiver array while the medium is illuminated by a plane wave.

In previous work [13], we have demonstrated that it is possible to use the matched field processing (MFP) to detect and localize mine and drum sized objects for various background and SNR scenarios. Here, we have derived analytical expressions of the performance bounds on estimates of object coordinates. The performance bounds basically indicate the best case scenario with the best estimator. Therefore, with these bounds available, it is possible to know if an object can be located with specified accuracy. Analysis of theoretical bounds have revealed that there exists an optimum inter-element spacing for which the bound is minimum. Thus, if an estimator is known to be bounded by CRB tightly, choosing the optimum inter-element spacing would minimize the estimation error. The analytical performance bounds are, then, verified with two simulation schemes: MUSIC based MFP, and ML based MFP. Simulations have verified that sample variances always lie above the values established by CRB. It has been observed that the difference between variances of estimates of object coordinates and their respective lower bounds gets smaller as the signal to noise ratio increases. Finally, it is shown that model mismatch in the object radius causes bias in estimating the object's radial coordinate. Furthermore, it is observed that if the object radius in the model is larger(smaller) than the true radius, variance of sample azimuthal coordinate $\hat{\theta}$ is smaller(larger).

As for the future work, we would like to extend present results in three directions. In the theoretical performance bound area, we will derive analytical expressions for the variances of estimation errors in MUSIC-MFP and extend the results of CRB analysis for multiple objects. In terms of simulations, we will run Monte-Carlo experiments to observe the change in error variances as the object location under the receiver array changes. For the model mismatch issue, we will extend the analysis to include mismatches in electrical properties of background and object. In order to account for mismatches due to object shapes, we would also like to analyze shape mismatch where the model and true object shapes are different.

APPENDIX A.

The scattered electromagnetic field from a cylindrical object with circular cross-section due to a plane wave incidence can be calculated using the harmonic expansions of the fields [17]. Given the center of the object (x_0, y_0) and incidence angle of the planewave ϕ_{inc} , the scattered field at the i th receiver location $\mathbf{r}_i = (r_i, \phi_i)$ in the coordinate system of object (Fig. 6) is given by:

$$E_s(\mathbf{r}_i) = \sum_{m=-\infty}^{\infty} j^{-m} c_m H_m^{(2)}(\beta r_i) e^{jm(\phi_i + \pi - \phi_{inc})} \quad (16)$$

where

$$c_m = -\frac{J_m(\beta \rho)}{H_m^{(2)}(\beta \rho)}$$

for metallic scatterers. The radius of the object is ρ and the wavenumber in the medium of propagation is β . The coefficients c_m decay quite rapidly as the number of harmonics increases. Thus, infinite sum in (16) can be truncated at M . The value of M is proportional to the radius of the object, $M \propto \beta\rho$. The variable M representing the number of harmonics here should not be confused with the same variable representing the dimension of the signal subspace in the body of the paper. It should be noted that the origin of coordinate system while calculating (16) is the center of the object, and coordinates of all sensors should be translated[†] to the object's coordinate system in polar form. Therefore, for every object location, this translation has to be carried out repeatedly.

Figure 6. Geometry for calculation of the scattered field and its derivatives

The derivatives with respect to object's polar coordinates (r, θ) have to be taken carefully, since we have to translate coordinates of receivers into object's local coordinate system, and then calculate the scattered field in that coordinate system. Therefore, we use the definition of the derivative operation to find the derivatives of the fields:

$$\frac{\partial \mathbf{E}_s(r, \theta)}{\partial r} = \lim_{\Delta r \rightarrow 0} \frac{\mathbf{E}_s(r + \Delta r, \theta) - \mathbf{E}_s(r, \theta)}{\Delta r} \quad (17)$$

and

$$\frac{\partial \mathbf{E}_s(r, \theta)}{\partial \theta} = \lim_{\Delta \theta \rightarrow 0} \frac{\mathbf{E}_s(r, \theta + \Delta \theta) - \mathbf{E}_s(r, \theta)}{\Delta \theta}. \quad (18)$$

Here $\mathbf{E}_s(r, \theta) = [E_s(\mathbf{r}_1), E_s(\mathbf{r}_2), \dots, E_s(\mathbf{r}_N)]^T$, where N is the number of sensors in the array. To find $\mathbf{E}_s(r + \Delta r, \theta)$ and $\mathbf{E}_s(r, \theta + \Delta \theta)$, the center of the object should be expressed in terms of its original center (x_0, y_0) when it is moved by an infinitesimal amount in r and θ direction. When the object is moved in r -direction by Δr , the new center (x_r, y_r) becomes:

$$x_r = x_0 + \Delta r \cos(\mu) \quad y_r = y_0 - \Delta r \sin(\mu).$$

[†]Translation of coordinates between two points is straightforward and is not discussed here

The angle μ can be expressed in terms of θ . When the object is moved in θ -direction by $\Delta\theta$, the new center (x_θ, y_θ) becomes:

$$x_\theta = x_0 - r\Delta\theta \cos(\psi) \quad y_\theta = y_0 - r\Delta\theta \sin(\psi)$$

where ψ can be expressed in terms of θ and $\Delta\theta$. Once the new object centers are found, all receiver coordinates can be translated to the new object centers where the scattered field is calculated. Having obtained $\mathbf{E}_s(r + \Delta r, \theta)$ and $\mathbf{E}_s(r, \theta + \Delta\theta)$, the derivatives of the scattered fields with respect to r and θ can be determined using (17) and (18), respectively.

Abstract

In this paper we explore the utility of multiscale and statistical techniques for detecting and characterizing the structure of localized anomalies in a medium based upon observations of scattered energy obtained at the boundaries of the region of interest. Wavelet transform techniques are used to provide an efficient and physically meaningful method for modeling the non-anomalous structure of the medium under investigation. We employ decision-theoretic methods both to analyze a variety of difficulties associated with the anomaly detection problem and as the basis for an algorithm to perform anomaly detection and estimation. These methods allow for a quantitative evaluation of the manner in which the performance of the algorithms is impacted by the amplitudes, spatial sizes, and positions of anomalous areas in the overall region of interest. Given the insight provided by this work, we formulate and analyze an algorithm for determining the number, location, and magnitudes associated with a set of anomaly structures. This approach is based upon the use of a Generalized, M-ary Likelihood Ratio Test to successively subdivide the region as a means of localizing anomalous areas in both space and scale. Examples of our multiscale inversion algorithm are presented using the Born approximation of an electrical conductivity problem formulated so as to illustrate many of the features associated with similar detection problems arising in fields such as geophysical prospecting, ultrasonic imaging, and medical imaging.

1 Introduction

The goal of many applied problems is the recovery of information regarding the structure of a physical medium based upon measurements of scattered radiation collected at the boundaries [8, 15, 19, 43, 48]. For some of these tomographic-type inverse problems, one seeks a complete description (in the form of an image in two dimensions or a volumetric rendering in 3D) of the structure of the medium. In other cases, however, the full reconstruction is not needed; rather, the ultimate objective is to extract the structure of areas in the medium which are, in some sense, anomalous; that is, regions where the nature of the medium differs from some prior set of expectations. This *anomaly detection problem* arises, for example, in geophysical prospecting where in many instances the fundamental issue is the determination of oil bearing regions in the earth and medical imaging where tumor detection is of import.

As discussed in [27, 29, 31, 33, 34, 44, 45] for many of the application areas previously cited, methods for solving the anomaly detection problem typically proceed by initially generating the full, pixel-by-pixel reconstruction and subsequently post-processing the results to determine the nature of anomalous structures. The necessity of generating a solution to the so-called “full inverse problem” however makes these schemes rather unattractive. Indeed, for many interesting applications, obtaining a full reconstruction of the medium presents a collection of well-known and extensively studied challenges [2, 3, 40] which suggest that solving this problem as the first step toward localizing anomalies should be avoided. In this paper we demonstrate the utility of a multiscale framework for explicitly solving the spatial anomaly detection problem in the context of linearized inverse scattering (also known as diffraction tomography [15]) applications.

The basis for solving the anomaly detection problem is the use of wavelet transforms and the statistical theories of optimal estimation and detection to develop both efficient algorithms for anomaly detection and localization and analytical insight into the nature of the problem and the limits of performance that result from the fundamental physics relating the characteristics of the medium to the observations. In [39, 40], we introduced the use of wavelet transforms and multiresolutional statistical techniques for overcoming many of the challenges associated with the solution of full reconstruction, linearized inverse electrical conductivity problems. Many of the results in [39, 40] followed from the use of multiscale, statistical regularization methods for the incorporation of prior knowledge into the inversion routine. The use of such prior statistical models automatically implies an assumption of some type of statistical regularity on the field and therefore fails to capture adequately the presence of anomalies or localized inhomogeneities. Thus, roughly stated, the problem considered in this paper is the detection, localization, and estimation of such anomalies superimposed on a background of known statistical structure and observed indirectly through the scattering measurements.

The consideration of the anomaly detection problem raises a variety of questions beyond those arising in the full reconstruction inverse problem. How many anomalies are there? Where are they located? What are their sizes? What are their amplitudes? Given answers to the first three of these problems, the fourth is a variant of the full inverse problem in which we focus our attention on determining the magnitudes of only the previously identified anomalous regions. The determination of the number, sizes and locations of the anomalous regions is, however, a potentially daunting collection of tasks as a result of the vast number of combinations of anomaly structures which, in principle, must be explored in the generation of a solution.

Over the past decade, significant work has been performed in the area of anomaly detection from tomographic-type measurements. In [44], Rossi and Willsky were concerned primarily with the use of estimation-theoretic analysis and algorithmic methods for determining the location of

a single object of known size and structure given noisy and sparse computed tomography (CT) measurements. Recently, these results have been extended by Devaney and co-workers [16, 17, 46] in consideration of diffraction tomography (DT) and exact scattering applications. More closely related to the problem of interest in this paper is the work of Bresler, Fessler and Macovski. In [5], the authors examined a 3D reconstruction problem from CT measurements in which the first step of their algorithm required the localization of an unknown number of anomalies of unknown structure. The solution to this problem presented in [5] was to estimate the required parameters for a pre-determined, maximum number of anomalies knowing that further processing would eliminate falsely identified anomalous regions.

In this paper, we present a scale-recursive algorithm for anomaly detection and characterization given DT-type data. Here, the tools of optimal hypothesis testing are used to make a sequence of anomaly detection and localization decisions starting at coarse scales, thereby allowing for the detection of spatially large anomaly structures and providing coarse localization of finer scale anomalies, and then moving to finer ones. This algorithm is significant for two reasons. First, this approach provides a computationally efficient and accurate means of localizing areas of anomalous behavior. Second, the anomaly characterization algorithm may be viewed as a highly efficient first stage in a larger image processing application. Specifically, the output of the algorithm could be refined (for example via the methods described in [5, 44] generalized to the case of diffraction tomography) by higher level processing stages concerned with issues such as identification, classification, or imaging. Toward this end, in Section 6.3, we present one way in which knowledge of the anomaly structures can be used to supplement the information in the prior statistical model in order to improve the output of a least-squares, pixel-by-pixel reconstruction of the region of interest.

In addition to the development of the scale-recursive processing algorithm, by using these same statistical techniques, we provide analysis of the anomaly detection problem that not only yields overall performance limits, but also guides the detection procedure. For example, we are able to define and determine the statistical distinguishability of a small scale, large amplitude anomaly from a larger scale, but smaller magnitude structure or a pair of closely spaced anomalies from a single, broader anomalous region. The use of the results from this analysis can then tell us at what scale and in which regions to terminate our detection procedure, i.e. when finer scale localization is unwarranted given the available data.

In Section 2, we present an overview of the particular anomaly detection problem of interest in this work. The formal definition of the anomaly detection problem as one of optimal hypothesis testing and a review of results from statistical decision theory is provided in Section 3. In Section 4 we demonstrate the utility of our framework in characterizing the *detectability* of an anomaly. Section 5 is devoted to the question of the *distinguishability* of anomalies as a function of their relative positions and structures. In Section 6 we develop and analyze a scale-recursive algorithm for anomaly detection, localization, and estimation, and present the results of its performance under a variety of experiment conditions. Conclusions reached in this paper and directions for further work are presented in Section 7.

2 A Multiscale Framework for Inverse Scattering

2.1 The Scattering Problem

The context in which we develop our anomaly detection algorithm is a low-frequency, two-dimensional inverse electrical conductivity problem illustrated in Figure 1 and similar to problems arising in the field of geophysical prospecting [23, 24, 48] and medical imaging using electrical impedance

Figure 1: Configuration of inverse conductivity problem. The electromagnetic sources (indicated by the black circles) emit time-harmonic waves into a lossy medium which subsequently are scattered by conductivity inhomogeneities located in the darkly shaded rectangle, A . The secondary fields are observed at one or both receiver arrays located on either vertical edge of region under investigation. Based upon these observations, the objective of the inverse problem is the reconstruction of the conductivity perturbation.

tomography [18–20, 22, 29–31, 43]. Here, we have an array of electromagnetic line-sources oriented perpendicularly to the page emitting time-harmonic, waves into a lossy medium. The electrical properties of this environment are assumed to be decomposed into the sum of an infinite, known, and constant background and a conductivity perturbation, g , with support restricted to region A in Figure 1. The fields from the transmitters are scattered by g , and the secondary fields are observed at one or both of the receiver arrays positioned on the vertical edges of region A . Based upon these observations, the objective of the problem is to detect and localize areas in the region of interest where the structure of g is, in a sense to be defined below, anomalous.

We consider the collection of eighteen scattering experiments defined in Table 1 where each such experiment produces a vector of measurements comprised of the in-phase and quadrature

components of the observed scattered field obtained over one of the two receiver arrays due to energy put into the medium from one of the sources operating at a particular frequency. As is shown in [9], the use of the first Born approximation yields the following linear relationship between the vector of observations associated with the i^{th} scattering experiment, y_i , and a discrete representation of the two dimensional conductivity anomaly, g

$$y_i = T_i g + n_i \quad i = 1, 2, \dots, 18 \quad (1)$$

where the matrices T_i encompass the (linearized) physics and n_i is an additive, zero-mean, uncorrelated, random vector representing the noise in the data. That is, the i^{th} noise is modeled as $n_i \sim \mathcal{N}(0, r_i I)$ where I is an appropriately sized identity matrix.¹ The discrete representation of the conductivity g is constructed using the so-called “pulse” set of basis functions where the conductivity is assumed to be piecewise constant over an $N_{g,x} \times N_{g,z}$ grid of square pixels covering A [26]. For future reference, we define the “stacked” system of data

$$y = Tg + n \quad (2)$$

where $y^T = [y_1^T \ y_2^T \ \dots \ y_{18}^T]$ with T and n defined accordingly.

Experiment number	Source Position	Frequency of source (Hz)	Receiver Array
1 – 6	0:20:100	$f_{HI} = 10,000$	Left
7 – 12	0:20:100	$f_{MID} = 1,000$	Left
13 – 18	0:20:100	$f_{LO} = 100$	Right

Table 1: Data set definitions for observation processes of interest in the paper. The notation $x : y : z$ indicated that the sources are distributed in y increments along a line from x to z .

2.2 A Multiscale Representation of the Problem

The detection techniques developed in Sections 4 – 6 are based upon a linear model relating multiresolution representations of g and n_i to a multiresolution representation the data, y_i . A scale-space representation of the problem has been chosen for two reasons. First, the matrices T_i in (1) are of the class which are made sparse in the wavelet transform domain [1, 4] thereby lowering the computational complexity of the detection algorithm in Section 6. Although not considered extensively in this work, such computational benefits are explored in [41]. Second, as we discuss below, a collection of useful and physically meaningful models for the non-anomalous behavior of the conductivity field are specified easily in the wavelet domain.

Following the work in [39, 40], orthonormal, discrete wavelet transform (DWT) [14] operators (matrices) \mathcal{W}_i and \mathcal{W}_g are used to move from physical to scale space in the following manner

$$\eta_i = \mathcal{W}_i y_i = (\mathcal{W}_i T_i \mathcal{W}_g^T)(\mathcal{W}_g g) + \mathcal{W}_i n_i \equiv \Theta_i \gamma + \nu_i \quad (3)$$

where $\mathcal{W}_g^T \mathcal{W}_g = \mathcal{W}_i^T \mathcal{W}_i = I$ follows from the orthonormality of the wavelet transformation [14, 35]. There are a variety of reasons why we may wish to use different transforms for the data than for g . First, from Figure 1, each data set is to be collected over a 1D array of receivers. Hence, \mathcal{W}_i will act on a one dimensional signal while \mathcal{W}_g is used to transform the 2D conductivity profile. Additionally, it may be the case that the lengths of each data record vary from one observation process to the next. Finally, analogously to the physical space case, we define the stacked systems

$$\eta = \Theta \gamma + \nu \quad (4)$$

where $\eta = [\eta_1^T \ \eta_2^T \ \dots \ \eta_{18}^T]^T$, Θ and ν are defined analogously and $\nu \sim \mathcal{N}(0, R)$ with $R = \text{diag}(r_1 I, r_2 I, \dots, r_{18} I)$.

¹The notation $x \sim \mathcal{N}(m, P)$ indicates that the random vector x has a Gaussian probability distribution with mean m and covariance matrix P .

2.3 Multiscale Prior Models

Recently there has been significant work in the use of fractal models for describing the spatial distribution of geophysical quantities. In [13], Crossley and Jensen explore the propagation of acoustic radiation in the Earth's crust using a velocity model composed of the sum of a deterministic profile and a fractal perturbation. In considering the distribution of hydraulic conductivity, Brewer and Wheatcraft [6] employ a wavelet-based model very similar to the one described below as a means of interpolating coarse scale observations of hydraulic conductivity to finer scales. Brown [7] relates both the electrical and hydraulic conductivities in the earth to a self-similar model for the height distribution in rock fractures and studies the resulting fluid and current flow patterns through such a formation. Finally, the propagation of electromagnetic radiation through media with fractal characteristics has been studied extensively by Jaggard and co-workers [32].

With this work as motivation, we use a stochastic, fractal-type model to describe the spatial distribution of the electrical conductivity in the absence of anomalies. While there are many self-similar models which may be used to describe the conductivity, results of Wornell [50], Tewfik [47], and Chou et al. [10–12] suggest that there exist a wide range of statistical models specified *directly* in the wavelet transform domain possessing the desired modeling characteristics and simple structures thereby making them quite attractive for use in signal and image processing applications.

Under the particular wavelet-based model of interest in this paper, the wavelet coefficients of the non-anomalous conductivity field, denoted by the vector $\tilde{\gamma}$, are taken to be uncorrelated, Gaussian random variables. That is, $\tilde{\gamma}$ is distributed according to

$$\tilde{\gamma} \sim \mathcal{N}(0, P_0) \quad (5)$$

where P_0 is a *diagonal* matrix whose nonzero entries are the variances of the corresponding wavelet coefficients. While a detailed description of the internal structure of P_0 is presented in [35, 50], the fractal-type behavior of the process is obtained by taking the variance of the wavelet coefficients to vary exponentially with scale. Coefficients in $\tilde{\gamma}$ governing the coarsest scale behavior of the conductivity have relatively large variances while fine scale components possess smaller variances.

3 Anomaly Detection as a Hypothesis Testing Problem

3.1 A Model for the Conductivity

The objective of the anomaly detection problem is to determine those areas in A where the behavior of g is anomalous in that in these regions g differs from some prior set of beliefs regarding the manner in which the conductivity is expected to behave. Thus, the conductivity g is decomposed as

$$g = \tilde{g} + \bar{g} \quad (6)$$

where \tilde{g} represent that portion of g consistent with our prior assumptions and \bar{g} encompasses the anomalous behavior of the conductivity; that is, the perturbation of the conductivity away from its non-anomalous structure. In the wavelet transform domain, (6) takes the form

$$\gamma = \mathcal{W}_g g = \mathcal{W}_g \tilde{g} + \mathcal{W}_g \bar{g} \equiv \tilde{\gamma} + \bar{\gamma}. \quad (7)$$

As will be seen in Sections 4–6, considerable insight into the anomaly detection problem is obtained through performance analysis carried out using anomaly structures of varying sizes (i.e. spatial scales) located in different regions of A . Also, the primary intent of the detection algorithm presented in Section 6 is to localize quickly and efficiently regions where anomalies are suspected to exist. As region A is pixelated into an $N_{g,x} \times N_{g,z}$ grid and because we perform anomaly localization through a process of spatial subdivision, we are lead naturally to consider a representation in which anomalous regions are defined to be superpositions of rectangular subsets of A .

Referring to Figure 2, the structure of the i^{th} anomaly in A is defined by its magnitude, a_i , its size, and its location in A . The area of an anomaly defines its *scale* in that small scale anomalies are

Figure 2: General structure of anomalous regions of interest in this paper. The magnitudes, a_1 and a_2 of the two anomalies shown here are proportional to the color of the corresponding rectangles.

correspondingly small in area and similarly for larger scale anomaly structures. Mathematically, the form for the anomalous behavior of the conductivity over the region A is

$$\bar{g} = \sum_{j=1}^{N_a} b_j a_j = Ba. \quad (8)$$

Here, N_a is the number of anomalous regions located in A , a_j is a scalar defining the magnitude of each anomaly, and b_j represents the discrete indicator function over the j^{th} rectangular region in \bar{g} . In (8), the column vector a represents the collection of anomaly amplitude coefficients while B is the matrix whose j^{th} column is b_j . In the wavelet transform domain, (8) is written as

$$\bar{\gamma} = \sum_{j=1}^{N_a} (\mathcal{W}_g b_j) a_j \equiv Ba \quad (9)$$

where $B = [\mathcal{W}_g b_1 \ \mathcal{W}_g b_2 \ \dots \ \mathcal{W}_g b_{N_a}]$. Finally, use of (7) and (9) in (4) yields the following relationship among the anomaly structures, the non-anomalous background \tilde{g} or $\tilde{\gamma}$, and the data

$$\eta = \Theta \bar{\gamma} + \Theta \tilde{\gamma} + \nu = \Theta Ba + \Theta \tilde{\gamma} + \nu \quad (10)$$

where, because $\tilde{\gamma}$ and ν are taken to be uncorrelated,

$$P_\eta = E[\eta \eta^T] - E[\eta]E[\eta^T] = \Theta P_0 \Theta^T + R. \quad (11)$$

Note that the analysis methods and algorithmic techniques presented in this work are based entirely on an observation model of the form in (10). In particular, the results in this paper are not dependent upon the assumption of rectangular anomalies; rather structures with arbitrary shapes and orientations can be employed in principle through the appropriate specification of the matrix B . Nonetheless, as will be seen in Sections 4–6 of this paper, rectangular structures prove to be highly useful for obtaining significant insight into the nature of the anomaly characterization problem and as the basis for an algorithm designed to extract this information from observed scattered fields.

To provide a normalized notion of the overall size of an anomaly, we define an SNR-type quantity called the *anomaly-to-background ratio* (ABR) which provides a measure of the energy in an anomaly relative to that of \tilde{g} . Mathematically, we have for an anomaly \bar{g} composed of a single rectangular region defined by the column vector b and with amplitude a

$$ABR^2 = \frac{\text{Power in } \bar{g}}{\text{Expected power in } \tilde{g}} = \frac{a^2 (b^T b)}{\text{tr}(\bar{P}_0)} \quad (12)$$

where $\text{tr}(M)$ is the trace of the matrix M and $\bar{P}_0 = \mathcal{W}_g^T P_0 \mathcal{W}_g$ is the covariance matrix of \tilde{g} .

As described in [40], under the Born approximation used to obtain (1), $g = \mathcal{W}_g^T \gamma$ represents a perturbation about a known, constant background conductivity, g_0 . From physical principles, the overall conductivity, $g_0 + g = g_0 + \tilde{g} + Ba$ must be greater than zero. Thus, in theory the elements of a may assume both positive as well as negative values so long as the positivity constraint is satisfied. To simplify matters, in this paper we assume that the a_i are strictly greater than zero corresponding to regions of locally higher conductivity than the background.

3.2 The M-ary Hypothesis Testing Problem

In Section 6, we consider a statistical decision-theoretic methodology for reconstructing $\bar{\gamma}$ which is based upon a sequence of M-ary Generalized Likelihood Ratio Tests (GLRT) as a means of localizing an unknown number of anomalous regions in A . The mathematical description of each such test begins with the formulation of the following M hypotheses, H_i for $i = 0, 1, 2, \dots, M-1$, corresponding to M different configurations of anomalous areas

$$H_i : \quad \eta = \Theta \mathcal{B}_i a_i + \Theta \tilde{\gamma} + \nu \quad i = 0, 1, 2, \dots, M-1. \quad (13)$$

Note that from (13) under H_i we have, $\eta \sim \mathcal{N}(\Theta \mathcal{B}_i a_i, P_\eta)$ where P_η is given by (11).

The hypothesis test is implemented as a rule which when given the data, indicates which of the H_i is true. Because it will be the case in Section 6 that the a_i are taken to be deterministic but unknown parameters, a standard likelihood ratio test solution to the hypothesis testing problem [49] cannot be employed in this context. Rather, we use a Generalized Likelihood Ratio Test (GLRT) [49] for performing the test. This procedure requires first that an estimate of each a_i be computed assuming that H_i is correct. As this problem is, in general, ill-posed, we choose here to use the following regularized, least squares estimate

$$\hat{a}_i = (\mathcal{B}_i^T \Theta^T P_\eta^{-1} \Theta \mathcal{B}_i + \alpha I)^{-1} \mathcal{B}_i^T \Theta^T P_\eta^{-1} \eta. \quad (14)$$

where the parameter α is used to control the degree of regularization.

Given \hat{a}_i , the hypothesis testing rule employed in this paper is

$$\text{Choose } H_i \text{ with } i = \begin{cases} 0 & \max_j L_j(\eta) < 0 \\ \arg \max_j L_j(\eta) & \text{otherwise} \end{cases} \quad (15)$$

where

$$L_j(\eta) = l_j(\eta) - l_0(\eta) \quad j = 1, 2, \dots, M-1 \quad (16)$$

and for $j = 0, 1, 2, \dots, M-1$

$$l_j(\eta) = \eta^T P_\eta^{-1} \Theta \mathcal{B}_j \hat{a}_j - \frac{1}{2} \hat{a}_j^T \mathcal{B}_j^T \Theta^T P_\eta^{-1} \Theta \mathcal{B}_j \hat{a}_j. \quad (17)$$

3.3 The Binary Hypothesis Testing Case

While the algorithm for extracting anomaly information is based upon the M-ary GLRT, much of the analysis of the anomaly detection problem is performed in the context of the *binary hypothesis testing* (BHT) framework in which two alternatives, $\bar{\gamma}_0 = \mathcal{B}_0 a_0$ and $\bar{\gamma}_1 = \mathcal{B}_1 a_1$, are compared.² Traditionally, the analysis of the BHT centers around the probability of detection, P_d and the false alarm probability, P_f . For the linear-Gaussian model considered in this work, it is shown in [49] that P_d and P_f are related to the various quantities defining the structure of the problem via

$$d = \text{erfc}_*^{-1}(P_f) - \text{erfc}_*^{-1}(P_d) \quad (18)$$

²Note that in the contexts where the binary testing scenario is to be explored, the values of a_0 and a_1 are assumed known so that a generalized test is not required.

where

$$d^2 = (\bar{\gamma}_1 - \bar{\gamma}_0)^T \Theta^T P_\eta^{-1} \Theta (\bar{\gamma}_1 - \bar{\gamma}_0) \quad (19)$$

$$\text{erfc}_*(x) = \int_x^\infty \frac{1}{\sqrt{2\pi}} e^{-t^2/2} dt. \quad (20)$$

Thus, based upon (18), we see that our ability to distinguish between two anomaly structures is intimately related to the Fisher discriminant, d , which has the interpretation of a “signal-to-noise” ratio [49]. Note that for a given P_f , larger d results in larger P_d and therefore better performance.

From (19) we observe that the performance of the binary hypothesis test is a function of both the geometric configurations, as captured in the matrices \mathcal{B}_i , and the magnitudes, a_i , of the two candidate anomaly structures. To better understand the role of these two factors, consider the case in which $\bar{\gamma}_i$ corresponds to a single rectangular region so that each \mathcal{B}_i is a column vector and each a_i is a scalar. Substituting (9) into (19) and expanding the quadratic yields

$$\delta_1^2 a_1^2 - 2\delta_{1,0} a_1 a_0 + \delta_0^2 a_0^2 - (\text{erfc}_*^{-1}(P_f) - \text{erfc}_*^{-1}(P_d)) = 0 \quad (21)$$

where

$$\delta_j^2 = \mathcal{B}_j^T \Theta^T P_\eta^{-1} \Theta \mathcal{B}_j \quad \text{for } j = 0, 1 \quad (22)$$

$$\delta_{1,0} = \mathcal{B}_1^T \Theta^T P_\eta^{-1} \Theta \mathcal{B}_0. \quad (23)$$

In [37], it is shown that when viewed as a function of a_0 and a_1 , (21) defines an ellipse the form of which is illustrated in Figure 3.³ This ellipse indicates that, given the geometry of the candidate anomalies, \mathcal{B}_0 and \mathcal{B}_1 , there are only certain combinations of a_0 and a_1 which will result in performance below that level dictated by a particular P_d and P_f . In fact, these points are precisely those that lie inside the plotted ellipse. Also, there exists a minimum level, $a_{1,0}^{\min}$ (depending on the geometric structures of *both* anomalies) such that for $\bar{\gamma}_1 = \mathcal{B}_1 a_1$ with $a_1 > a_{1,0}^{\min}$, the binary hypothesis test will achieve or exceed the P_d and P_f performance figures *independent* of a_0 .

4 Detectability Analysis

The first issue we address in conjunction with the anomaly detection problem is that of the detectability of an anomaly as a function of location, spatial size, and amplitude. After defining a particular collection of anomaly structures, a set of binary hypothesis testing problems are explored in which H_0 corresponds to there being no anomaly in the region while under H_1 , a particular member of our anomaly collection is assumed to be present. The objective of the detectability analysis is to determine the minimum magnitude each such structure must possess to guarantee a prespecified level of performance from the binary hypothesis test.

Detectability is of interest due to the physics governing the relationship between the observations, η , and the conductivity, γ and the constrained experimental conditions in which data are collected only along the vertical edges of A . From these facts, it is not expected that arbitrarily small (in scale and magnitude) anomalies will be detectable with arbitrary precision throughout A . Rather, we anticipate that small anomalies should be readily detected only close to the observation points while interior to region A small scale structures would require significantly larger magnitudes to be as detectable as their counterparts closer to the edges.

With this intuition in mind, we consider a family of anomaly structures generated by a set of dyadic tessellations of A . For example, with $N_{g,x} = N_{g,z} \equiv N_g = 16$, we take as \mathcal{J}_1 the set of N_g^2 indicator functions which are one over single pixels in A and zero elsewhere. Analogously, \mathcal{J}_2 is the collection of $N_g^2/4$ characteristic functions over disjoint 2×2 sized regions of A . Thus, in general

³For illustrative purposes only, in Figure 3 it is assumed that the major axis of the ellipse is oriented at an angle less than 90° from the a_0 axis. While this is not necessarily the case, the analysis which follows is independent of which axis is the major and which the minor.

Figure 3: The structure of the ellipse defined by (21). The axes represent the magnitudes of anomaly structures in a binary hypothesis testing problem. As discussed in Section 2, a_0 and a_1 are taken to be nonnegative so that only the first quadrant is shown in this illustration. Here a_1^* is the minimum amplitude of $\tilde{\gamma}_1$ required to detect this structure when the alternate hypothesis is $\tilde{\gamma}_0 = 0$ for a BHT with prespecified P_d and P_f . The value $a_{1,0}^{min}$ is the minimum intensity of $\tilde{\gamma}_1$ required to ensure that for *any* $\tilde{\gamma}_0$ the performance of the resulting BHT meets or exceeds that defined by P_d and P_f .

\mathcal{J}_m (for m an integral power of 2) is the set of $(N_g/m)^2$ non-overlapping square regions of size $m \times m$ completely covering A . Finally, we define \mathcal{J} as the union of all \mathcal{J}_m .

To begin our analysis of detectability, for each anomaly structure in \mathcal{J} , we consider a collection of binary hypothesis testing problems where the two hypotheses in the j^{th} problem correspond to the situations in which no anomaly is present in A or a scaled version of the j^{th} element of \mathcal{J} is in A . Recalling (13), these alternatives take the form

$$H_0 : \eta = \Theta\tilde{\gamma} + \nu \quad (24a)$$

$$H_{1,j} : \eta = \Theta\mathcal{B}_j a_j + \Theta\tilde{\gamma} + \nu. \quad (24b)$$

The goal of our detectability analysis then is to determine for each anomaly structure in \mathcal{J} , the minimum value of a_j , denoted a_j^* , such that the above hypothesis test attains a certain level of performance as specified by P_d and P_f .

The primary quantity used to characterize the performance of the binary hypothesis test in (24a)–(24b) is the Fisher discriminant discussed in the previous section which here takes the form

$$d_j^2 = a_j^2 (\mathcal{B}_j^T \Theta^T P_\eta^{-1} \Theta \mathcal{B}_j) \equiv a_j^2 \delta_j^2 \quad (25)$$

where δ_j^2 is defined in (22) and represents the Fisher discriminant for the unit amplitude anomaly over the j^{th} member of \mathcal{J} . Now, for a given P_d and P_f , (18) and (25) are combined to give the following expression for a_j^* :

$$a_j^* = \frac{\text{erfc}^{-1}(P_f) - \text{erfc}^{-1}(P_d)}{\delta_j}. \quad (26)$$

In Figure 4, a_j^* are plotted for all anomalies in \mathcal{J} for the case in which data from the 18 experiments described in Table 1 at an SNR of 10 are available and where P_d is set to 0.95 and P_f is 0.05. In this work, the SNR associated with the anomaly-free observation process $\eta_i = \Theta_i \tilde{\gamma} + \nu_i$ with $\nu_i \sim (0, r_i^2 I)$ and $\gamma \sim (0, P_0)$ is defined as

Figure 4: Value of a_j^* for all anomaly structures in \mathcal{J} where the data from the experiments described in Table 1 at an SNR of 10 are used as input to the likelihood ratio test. Here, we have $P_d = 0.95$ and $P_f = 0.05$. Note that the scales in these images are all different with a^* decreasing significantly as the size of the anomalies increases.

$$SNR_i^2 = \frac{\text{Power per pixel in } \Theta_i \gamma}{\text{Power per pixel in } \nu_i} = \frac{\text{tr}(\Theta_i P_0 \Theta_i^T)}{N_g r_i^2}. \quad (27)$$

Thus, each 1×1 pixel in Figure 4(a) corresponds to an anomaly in \mathcal{J}_1 with the intensity of that pixel proportional to a_j^* . In all four cases, we see that near the middle of the region, the magnitude required to obtain the desired level of performance in the binary hypothesis test is significantly larger than that required near the vertical edges i.e. where the sources and receivers are located. For vertical values roughly in the range $40 \leq z \leq 60$, this effect is somewhat smaller. Also, as the areas of the anomalies increase, the required magnitudes decrease. This coincides with the intuition that large scale structures should be easier to detect than their fine scale counterparts. Finally, the ABR values in Figure 4 are quite small with the median values all less than 0.9. This implies that our statistical approach toward anomaly detection should prove quite advantageous in detecting relatively small amplitude conductivity anomalies.

To explain the behavior of a_j^* , we note that as described in [40] the low and medium frequency

kernels are most sensitive to the conductivity structure over the horizontal range $0 \leq x \leq 50$ so that the required magnitude for an anomaly to be “seen” in this area should be relatively low. The smaller values of a_j^* in the region $40 \leq z \leq 60$ are due primarily to the combined coverage of this region by more observation kernels, T_i , than is the case for the top and bottom edges.

5 Distinguishability Analysis

In this section, we explore issues associated with our ability to successfully distinguish between pairs of candidate anomalies in order to obtain quantitative insight into the ambiguity which exists in attempting to differentiate between anomalous structures of differing sizes, locations, and magnitudes. The results of this work then are used both in the formulation as well as the analysis of the detection algorithm in Section 6.

Before proceeding with the analysis, we note that the issue of distinguishability has been considered previously in the context of electrical impedance tomography [18, 22, 29]. In that work, distinguishability was examined in a deterministic setting where observation perturbation was modeled as a bounded but otherwise unknown signal. Under such a model, two conductivity profiles were defined to be distinguishable if the norm of the difference between the data sets produced by each exceeded the noise level. The notion of distinguishability developed below is rather different as it rests upon a statistical model for both the additive measurement noise and background perturbations in the medium’s conductivity.

The mathematical formulation of the distinguishability problem of interest in this work follows directly from Section 3.3. We begin by considering the following binary hypothesis testing problem

$$H_j : \eta = \Theta \mathcal{B}_j a_j + \Theta \tilde{\gamma} + \nu \quad (28a)$$

$$H_i : \eta = \Theta \mathcal{B}_i a_i + \Theta \tilde{\gamma} + \nu. \quad (28b)$$

The primary tool for our distinguishability analysis is the quantity $a_{i,j}^{min}$ defined in Section 3.3 to be the smallest value of a_i such that the performance of the binary hypothesis test in (28a)–(28b) meets or exceeds that defined by $P_{d,i,j}$ and $P_{f,i,j}$ independent of the amplitude of a_j . Finally, for all experiments and for all i and j of interest in this section, $P_{d,i,j}$ is equal to 0.95 and $P_{f,i,j} = 0.05$.

In Figures 6, $a_{i,j}^{min}$ is shown as a function of $j \in \mathcal{J}$ in the case where the geometric structure of anomaly $\tilde{\gamma}_i$ is given in Figure 5(a). Similarly, $a_{i,j}^{min}$ is displayed for the anomaly geometry of Figure 5(b) in Figure 7. Essentially these two examples demonstrate the manner in which the ability to differentiate structures is dependent upon the spatial position of the anomalies in region A . In both cases, we see that the largest values of $a_{i,j}^{min}$ are associated with hypothesis tests in which $\tilde{\gamma}_i$ is compared to a second, relatively close-by anomaly structure; however, these amplitudes are roughly twice as large for the structure located toward the middle of the region than for the anomaly closer to the source/receiver arrays.

In Table 2, the ABRs corresponding to the largest and smallest values for $a_{i,j}^{min}$ in Figures 6 and 7 are shown. That is for i fixed, the entries in the first column of Table 2 are the anomaly-to-background ratios generated by

$$a_i^{max,min} = \max_j a_{i,j}^{min}$$

while those of the second column are associated with

$$a_i^{min,min} = \min_j a_{i,j}^{min}.$$

Note that if a_i is greater than $a_i^{max,min}$, a BHT with the anomaly $\tilde{\gamma}_i$ given by $\mathcal{B}_i a_i$ will meet the $P_{d,i,j}$ and $P_{f,i,j}$ specification regardless of both the amplitude as well as the location of γ_j , i.e. the performance will be independent of j . On the other hand if a_i is less than $a_i^{min,min}$ then for every j there will be some range of amplitudes a_j for which the performance specifications will

(a) First anomaly structure to be analyzed in distinguishability problems

(b) Second anomaly structure to be analyzed in distinguishability problems

not be achieved. Now, from the first row of Table 2, we see that for an anomaly with geometric structure in Figure 5(a), an ABR of 2.11 ensures that any binary hypothesis test in which this structure is compared to a member of \mathcal{J} will meet the performance specifications of $P_{d,i,j} = 0.95$ and $P_{f,i,j} = 0.05$. Alternatively, if the ABR falls below 0.56 then for all structures in \mathcal{J} , (i.e. all

Figure 6: Images of the minimum magnitude of the anomaly in Figure 5(a) to guarantee a $P_d = 0.95$ and $P_f = 0.05$ in binary hypothesis tests involving this anomaly structure and elements of \mathcal{J} . Note that while the scales in these images are different the magnitudes are all less than 2.5.

\mathcal{B}_j) the performance of the BHT will fail to meet the $P_{d,i,j}$ and $P_{f,i,j}$ requirements for some range of a_j . Similar results hold for the second anomaly structure located closer to the left side except that in this case, the required values of the ABR are smaller.

Anomaly $\tilde{\gamma}_i$	Maximum ABR	Minimum ABR
Rightmost (Figure 5(a))	0.49	0.24
Leftmost (Figure 5(b))	2.11	0.56

Table 2: Minimum and maximum anomaly-to-background ratio associated with the smallest and largest values for $a_{i,j}^{min}$ for the anomaly structures in Figure 5(a) and 5(b).

Figure 7: Images of the minimum magnitude of the anomaly in Figure 5(b) to guarantee a $P_d = 0.95$ and $P_f = 0.05$ in binary hypothesis tests involving this anomaly structure and elements of \mathcal{J} . Again, the scales in (a) through (d) are all different; however the overall range of values is between 0.9 and 1.3.

6 A Multiscale Algorithm for Anomaly Characterization

In this section we describe and analyze a multiscale, decision-theoretic algorithm to determine the positions, sizes and magnitudes of an unknown number of anomalous structures in region A . We begin with a small collection of relatively large rectangular areas in which anomalies *may* be located. Each region represents a top-level node in a tree of finer-scale subdivisions of A . We next use a decision-directed procedure for determining how best to move from one level of the tree, corresponding to a collection of coarse-scale hypotheses, to the next level in which anomalies are better localized using smaller-scale rectangles. The result of this procedure is a collection of rectangular areas of varying sizes and positions where we believe anomalies exist. To limit the number of targeted areas which contain no anomalies, the algorithm concludes with a pruning step where we also estimate the magnitudes of the final group of chosen anomaly structures.

6.1 A Scale Recursive, Decision Driven Detection Algorithm

The first step in our detection algorithm involves an M-ary Hypothesis test in which we consider 10 ways to subdivide A in order to better localize anomalous structures. As seen in Figure 8 the first configuration corresponds to the presence of a coarse scale anomaly with support over all of A . This particular structure indicates that *no* further decomposition is warranted. The next four possibilities each allows for a single anomaly localized to the top, bottom, left and right halves of A respectively. Because anomalies might lie both in the left/right as well as the top/bottom halves, the sixth and seventh structures in Figure 8 are included. Since multiple anomalies may be present in the region, the eighth configuration corresponds to the presence of one anomaly located in the left half and one in the right while the ninth presents the analogous situation but for the top and the bottom. Finally, for this initial decomposition only, we consider the last case where we conjecture that *no* anomalous regions exists in A .

Given the 10 choices in Figure 8, we formulate a 10-ary hypothesis testing problem the solution of which is obtained using the Generalized Likelihood Ratio Test (GLRT) discussed in Section 3.2. Using (17) we compute the values of the generalized log-likelihood function for each of the hypotheses under consideration. From Figure 8, if H_0 is chosen, no further decomposition occurs and we conclude that there is a single anomaly covering the entire region of interest. If H_9 is selected, the algorithm terminates with the conclusion that there is no anomaly in region A . Otherwise, we decompose that hypothesis with the largest generalized log-likelihood value.

Our scale-recursive decomposition of A continues by essentially repeating the hypothesis testing procedure for each of the subregions indicated by the initial 10-ary hypothesis test as being of interest. For example, consider the case where H_3 is chosen. Referring to Figure 8, this selection corresponds to an anomaly located in the left half of A . In an effort to better localize the anomalous activity in this region, we consider an M-ary hypothesis test similar to that described in the previous paragraph but where the underlying area involved in the decomposition is now the left half of A rather than all of A . While the subdivision is of a rectangular region as opposed to a square area, the form of the hypotheses fundamentally remains the same as in those displayed in Figure 8 in that we consider the possibilities of anomalies located in the top, bottom, left, and right halves, etc. of this long and thin structure. We note that the first of these nine hypotheses, H_0 , corresponds to the case where no further decomposition of the left half is warranted and thus serves as a means of terminating the scale recursive search over this region of A . Instead of ten, there are only nine hypotheses as we no longer include the possibility that no anomaly exists in the left half of A since the previous iteration indicated that *somewhere* in the left side there exists an anomaly.

This nine-hypothesis GLRT is repeated recursively beginning with the regions selected in the initial decomposition of A . This decision-theoretic localization process continues until no further subdivision in a particular region is warranted based upon the selection of the H_0 hypothesis at some stage of the process or because no addition refinement is possible because the structures under consideration are too small. Thus at the end of our scale-recursive decomposition of A we have a collection of rectangular regions where anomalous structures are likely to exist. We then collect the wavelet-domain representations of these rectangles as columns in a matrix labeled \mathcal{B}_{leaf} .

To limit the number of false alarms generated by our detection algorithm, we retain only those structures in \mathcal{B}_{leaf} corresponding to sufficiently “detectable” anomalies. Specifically, we begin computing \hat{a}_{leaf} , the amplitudes associated with \mathcal{B}_{leaf} , using (14) with \mathcal{B}_i replaced by \mathcal{B}_{leaf} . Next, for each column of \mathcal{B}_{leaf} , we calculate the minimum required amplitude to guarantee a set level of performance from a detectability-type hypothesis test developed in Section 4 (here we use $P_d = 0.80$ and $P_f = 0.10$). The final estimated anomaly structure generated by our algorithm is composed of

Figure 8: Geometric structures of nine possible decompositions used at each stage of our decomposition of A . The darkly shaded regions indicate the areas where anomalous structures are hypothesized to exist. While the figure illustrates the decomposition of a square region, analogous subdivision schemes are used for rectangular areas as well with the fundamental idea being the presence of anomalies in the top, bottom, left, right, etc.

those columns of \mathcal{B}_{leaf} and elements of a_{leaf} corresponding to anomalies whose amplitudes exceed this required minimum and we label these estimates $\hat{\mathcal{B}}$ and \hat{a} respectively.

6.2 Algorithm Analysis

The scale-recursive detection algorithm described in Section 6.1 requires that we be able to identify successfully large-scale structures covering the true, smaller-scale anomalies. The results of the distinguishability analysis suggest that the correct large-scale structures are likely to be selected. Indeed, Figures 6 and 7 showed that the largest values of $a_{i,j}^{min}$ corresponded to those j in \mathcal{J} which overlap anomaly i . From this, we conclude that small-scale anomalies “look” most like those large-scale counterparts located in the same region of A .

To further verify this intuition, we undertake a more detailed performance analysis of the GLRT used in the detection algorithm. Specifically, we consider the case where a single anomaly, \bar{g}^* , of unknown amplitude exists at some fine scale and we perform a generalized binary hypothesis in which the two hypotheses correspond to coarse scale structures one of which covers \bar{g}^* and one of which does not. We are interested in examining how the probability of correctly choosing the overlapping structure (which we call the probability of detection for these experiments) using the GLRT of Section 3.2 varies with the scale and position of the non-overlapping alternate as well as the amplitude of the true anomaly. High detection probabilities reflect favorably on the GLRT-based approach of the scale-recursive algorithm.

Following the notation of (17), let $l_1(\eta)$ be the statistic associated with the overlapping anomaly hypothesis and $l_0(\eta)$ be the statistic for the non-overlapping case. From (15) and (16), the probability of choosing the overlapping structure given knowledge of $\bar{\gamma}^* = \mathcal{W}_g \bar{g}^*$ is

$$\text{Prob}[L_1(\eta) > 0 | \bar{\gamma}^*] = \text{Prob}[l_1(\eta) - l_0(\eta) > 0 | \bar{\gamma}^*]. \quad (29)$$

Upon substituting (14) into (16) and using (17), straightforward linear algebra demonstrates that the random variable $L_1(\eta)$ may be written as

$$L_1(\eta) = x_1^2(\eta) - x_0^2(\eta) \quad (30)$$

where the two-vector $x(\eta) = [x_1(\eta) \ x_0(\eta)]^T$ is

$$x(\eta) = \mathcal{B}_{10}^T \Theta^T P_\eta^{-1} \eta \sim \mathcal{N}(\mathcal{B}_{10}^T \Theta^T P_\eta^{-1} \Theta \bar{\gamma}^*, \mathcal{B}_{10}^T \Theta^T P_\eta^{-1} \Theta \mathcal{B}_{10}) \quad (31)$$

and for $j = 0, 1$

$$\mathcal{B}_{10} = \begin{bmatrix} s_1 \mathcal{B}_1 & s_0 \mathcal{B}_0 \end{bmatrix} \quad (32a)$$

$$s_j^2 = \frac{1}{2} [P_j(1 + \alpha P_j)] \quad (32b)$$

$$P_j = (\mathcal{B}_j^T \Theta^T P_\eta^{-1} \Theta \mathcal{B}_j + \alpha)^{-1} \quad (32c)$$

From (30), $\text{Prob}[L_1(\eta) > 0 | \bar{\gamma}^*] = \text{Prob}[|x_1(\eta)| > |x_0(\eta)| | \bar{\gamma}^*]$ which is the integral of the probability density function for $x(\eta)$ defined in (31) over the shaded region in Figure 9.

In Figure 10, detection probabilities are displayed for binary hypothesis tests where \bar{g}^* is the structure in Figure 5(a) and the hypotheses are pairs of structures from \mathcal{J} . For example, the shade of dark region in the lower left corner in Figure 10(a) is $\text{Prob}[L_1(\eta) > 0 | \bar{\gamma}^*]$ for the BHT where the first hypothesis is the large structure overlapping the true, smaller size anomaly (represented by the white region in Figure 10(a)) and the alternate hypothesis is the 8×8 pixel lower left corner of A . Similar interpretations hold for the other two dark areas in Figure 10(a) and for each of the smaller square areas in Figures 10(b)–(c). For all of these images, the ABR for the true, small anomaly is set to 1.5. Figures 10(a)–(c) indicate the manner in which the detection performance of the GLRT-based algorithm depends upon the scale of the hypotheses relative to that of the true anomaly. At the coarsest scale, detection probabilities are about 60%. However, for all finer scales, P_d rises sharply with the lowest values confined to structures which are close to the true anomaly.

In Figure 10(d), we display the minimum P_d at each scale as a function of true anomaly's ABR. For example, the points on each of the three curves at an ABR of 1.5 are the minimum P_d values in each of the three images in Figure 10(a)–(c). From these curves we see that at the coarsest scale, even at high ABRs, the detection probabilities reach about 80%. As expected, when the hypotheses are drawn from the finer scales, the minimum P_d rises quickly to close to 100%.

The results in Figures 10 indicate that if the scale-recursive anomaly detection algorithm developed in Section 6.1 correctly identifies the coarse scale structures overlapping the true anomalies, then the detection performance at finer scales should be quite good even at ABRs less than 1. Also, because the *lowest* detection probabilities at fine scales are associated with structures close to the true structure, it is anticipated that the scale-recursive detection algorithm should be very successful in producing estimates of anomalies which are “sufficiently close” to the truth if not exactly the truth. This idea will be made more precise in Section 6.3.

The analysis in this section indicates that the primary difficulty associated with the algorithm is

Figure 9: Integration region in $x_1 - x_0$ space for evaluation of $\text{Prob}[L_1(\eta) > 0 | \bar{\gamma}^*]$ in (29)

that coarse scale detection probabilities can be low. To overcome the potential problem of selecting the wrong area or areas of A for further refinement at coarse scales we modify the scale-recursive algorithm in the following manner. At the opening stage of the algorithm, rather than accepting the *single* hypothesis with the largest generalized log-likelihood value, we consider further refinement of A based upon those hypotheses corresponding to the *four* largest log-likelihood values (excluding H_0 and H_9). As will be seen in Section 6.3, despite the additional computational requirements of this approach, the overall complexity of the algorithm remains rather low. Finally, we note that one could extend this strategy of keeping additional structures for further refinement to more than just the first stage of the algorithm and could retain fewer or greater than four alternatives; however for the application of interest here, the choices described above were sufficient.

6.3 Examples

In this section, we examine the performance of the scale-recursive algorithm described in Sections 6.1 and 6.2. First, we use Monte Carlo studies to verify the ability of this approach to detect anomalous structures. The quantities of interest here are the sample probability of detection, \bar{P}_d , the sample average value of the number of false alarms per pixel \bar{P}_f , and the sample probability of error, \bar{P}_e . We say that a particular rectangular anomaly, $\bar{\gamma}^*$, has been detected if there exists a column in \hat{B} which is sufficiently close to $\bar{\gamma}^*$. Specifically, we define a “region of ambiguity” associated with the anomaly structure currently under investigation. This area is constructed such that anomaly structures identified in this region are “essentially indistinguishable” from the true anomaly. More formally, we compute the probability of successfully distinguishing $\bar{\gamma}^*$ from each member of \mathcal{J} in a binary hypothesis test of the form in (28a)–(28b). For each such test, the amplitudes of the two anomalies are chosen so that relative to the anomaly-free background, the two structures are equally detectable (i.e. they individually have the same d^2 value as defined with $P_d = 0.85$ and $P_f = 0.10$ in (18) and (26).) A pixel in A is said to be in the ambiguity region if (1) there exists a member of \mathcal{J} which is nonzero on that pixel and (2) the probability of distinguishing that element of \mathcal{J} from $\bar{\gamma}^*$ is below a given threshold, taken as 0.85 for all problems considered in

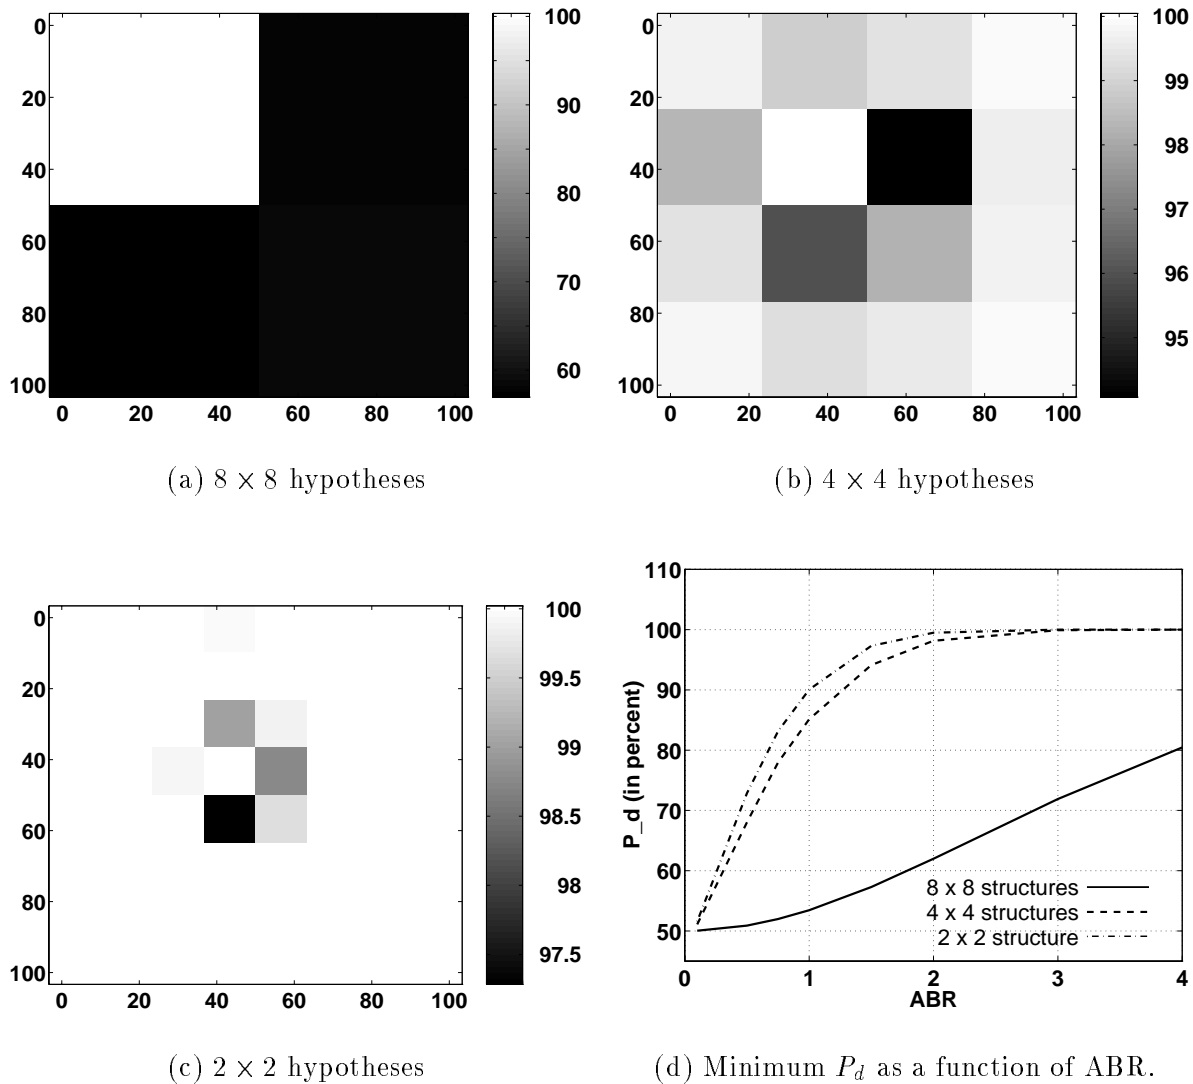

Figure 10: In (a)–(c) detection probabilities are displayed for binary hypothesis tests where \bar{g}^* is the structure in Figure 5(a) and the hypotheses are pairs of structures from \mathcal{J} . For each such test, one of the hypotheses is a larger scale structure overlapping \bar{g}^* while the second structures is from the same scale as the first but is disjoint from the pixels of \bar{g}^* . The shade of each square in (a)–(c) is the probability of correctly choosing the overlapping structure when the alternate is the anomaly occupying the square under investigation. The ABR for the true structure is 1.5. The minimum P_d at each scale as a function of true anomaly's ABR is shown in (d).

this section. Finally, for an estimated structure to be called a detection the area of intersection between it and the region of ambiguity must be at least a quarter of the area of the estimated structure. Such a definition implies a constraint on the localization of an estimated anomaly in both space and scale before we will call it a detection. As an example, the region of ambiguity at $P_d = 0.85$ associated with the anomaly structure in Figure 5 is displayed in Figure 11. The elements of $\hat{\mathcal{B}}$ which do not correspond to detections are taken to be false alarms and the per-pixel false alarm rate, \bar{P}_f , is defined as the total number of false alarm pixels divided by the number of

pixels in region A . Finally, the sample probability of error is $\bar{P}_e = 1 - \bar{P}_d + \bar{P}_f$.

Figure 11: Region of ambiguity for structure shown in Figure 5 for $P_d = 0.85$.

We also examine the computational complexity of the scale-recursive algorithm. The complexity of the algorithm is quantified in terms of the number of Generalized Likelihood Ratio Tests (GLRTs) which must be performed in the processing of the data. As the spatial decomposition of region A is driven by the noisy data, the number of GLRTs will vary from one data set to the next. Thus, for a particular \bar{g}^* , the computational performance is based upon the average number of required GLRTs required per iteration of the corresponding Monte-Carlo.

Finally as discussed in Section 1, the detection algorithm results are used to improve the solution to the full reconstruction inverse problem. From our model for γ in (6), the estimate of the overall conductivity is the sum of the estimates of $\bar{\gamma}$ and $\tilde{\gamma}$, denoted $\hat{\gamma}$ and $\hat{\tilde{\gamma}}$ respectively, where $\hat{\gamma} = \hat{\mathcal{B}}\hat{a}$ is provided by our scale-recursive detection algorithm. Now, the linear least-squares estimate (LLSE) of $\tilde{\gamma}$ developed in [37,40] is based upon the assumption that *no* anomalies exist in the data; however, the output of the detection algorithm provides additional information through $\hat{\tilde{\gamma}}$ as to the structure of the conductivity field. To make use of the information in order to improve the estimate $\hat{\gamma}$, we define $\hat{\tilde{\gamma}}_c$ as the LLSE of $\tilde{\gamma}$ based upon a “corrected” data set in which the effects of $\hat{\tilde{\gamma}}$ have been removed. Mathematically this corrected estimate takes the form

$$\hat{\tilde{\gamma}}_c = P\Theta^T R^{-1} [\eta - \Theta\hat{\mathcal{B}}\hat{a}] \quad (33)$$

where $P = (\Theta^T R^{-1} \Theta + P_0^{-1})^{-1}$ is the error covariance matrix for nominal LLSE. Thus, the estimate of the overall conductivity field is

$$\hat{\gamma} = \hat{\tilde{\gamma}}_c + \hat{\tilde{\gamma}} = P\Theta^T R^{-1} \eta + [I - P\Theta^T R^{-1} \Theta] \hat{\mathcal{B}}\hat{a} \quad (34)$$

where we recognize the term $P\Theta^T R^{-1} \eta$ as the uncorrected LLSE estimate [49].

Unless otherwise stated, the data upon which the examples are based are generated using the Born-based measurements model in (2) for the scattering experiments described in Table 1. For all cases consider, the background conductivity, g_0 , is set to 1 S/m and at the highest ABRs of interest, the anomaly amplitudes are only 0.7 S/m. As discussed in [25], under these circumstances the Born approximation is known to be valid. In Section 7, we discuss issues associated with extending the work in this paper to account for the underlying non-linearity associated with the inverse conductivity problem. Finally, for all experiments the parameter α in (14) is set to 0.25.

6.3.1 The Single Anomaly Case

We begin by considering the case where it is known that there is a single anomaly of unknown amplitude and location in region A . Given that there is only one structure, the combinatorial complexity associated with an “exhaustive search” for the anomaly is sufficiently low that we shall compare both the detection/false-alarm performance as well as the complexity of the scale-recursive approach against an alternate algorithm akin to a multi-scale matched filter. This algorithm detects the single anomaly by computing the GLRT for each of the structures in family \mathcal{J} taking that element of \mathcal{J} associated with the largest GLRT statistic as the estimate. Because this method is multiscale in nature and has a fixed number of GLRTs per Monte-Carlo iteration (since there are a fixed number of structures in \mathcal{J}) it allows for a fair comparison against which we can judge the performance of the scale-recursive algorithm. For the scale-recursive method, we shall account for the knowledge that there is only a single anomaly in A by retaining only the column of \mathcal{B}_{leaf} associated with the most likely anomaly structure. Finally, for this example, the true anomaly structure is shown in Figure 5 and the SNR for all scattering experiments is 10.

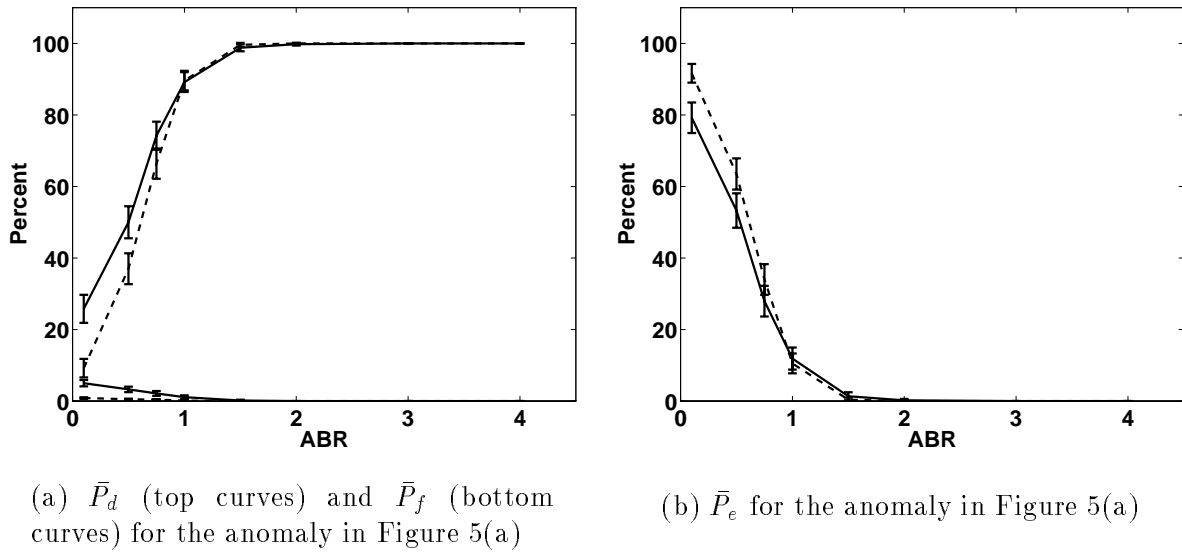

In Figure 12 we show \bar{P}_d , \bar{P}_f , \bar{P}_e and the average number of GLRTs per Monte-Carlo iteration as a function of anomaly-to-background ratio obtained after 500 Monte-Carlo iterations. The solid lines are the results for scale-recursive algorithm and the dashed lines indicate the performance of the multi-scale exhaustive search procedure. Figure 12(a) indicates that at low ABRs, the scale-recursive approach tends to have a higher detection probability than the exhaustive search with a slightly higher probability of false alarm. Even for the low ABR of 0.50, \bar{P}_d is well above 50% and rises to above 90% for ABR values greater than one. At high ABRs the performance of the two algorithms is about the same. Despite the slightly higher \bar{P}_f of the scale-recursive approach, the overall error probability is lower for the scale-recursive method at these small ABRs. Finally, from 12(c) the computational complexity of the scale-recursive characterization algorithm is seen to be roughly constant across the ABR range at 65% that of the exhaustive search.

In Figure 13(a) we display one realization of $g = \bar{g} + \tilde{g}$ obtained in our Monte Carlo process at an ABR of 1.5. Using the LLSE to perform the full reconstruction as in [40] results in the image in Figure 13(b). By incorporating the results of the scale-recursive detection algorithm into the inversion procedure through the use of (34), we obtain the estimate of the overall conductivity field shown in 13(c). Thus, successful identification of the highly parameterized anomaly structures can significantly improve localization both in space and scale and the GLRT procedure results in an accurate estimate of the structure’s amplitude. Also, the details in the remainder of the estimate do in fact reflect the coarse scale, fractal features of the conductivity profile in Figure 13(a).

6.3.2 The Multiple Anomaly Case

We now turn our attention to the case where multiple anomalies exist in region A .⁴ Lifting the single anomaly assumption causes the computational complexity of an exhaustive-search-type of approach to be prohibitive in that one would be required to examine the likelihood of all combinations of all non-overlapping, structures in a collection such as \mathcal{J} assuming separately $n = 1$ then $n = 2$ through $n = N_{max}$ anomalies exist in region A where N_{max} is a pre-determined maximum number of anomalies. Thus, here we present only the results of the scale-recursive detection algorithm. In particular, we explore the performance for the anomaly configuration in Figure 14.

⁴Note that in this multi-anomaly case, the ABR is used to determine the magnitude of each structure individually. For example at an ABR of one, the amplitude of the left anomaly is set so that if it were the only structure in the medium, the ABR would be one.

(c) Average number of GLRTs per Monte-Carlo iteration for anomaly detection algorithms for the anomaly in Figure 5(a).

Figure 12: Performance curves as a function of ABR obtained after 500 Monte-Carlo iterations for the anomaly in Figure 5(a). Solid lines = results for scale-recursive algorithm. Dashed lines = results for multi-scale exhaustive search. The error bars are drawn at the plus/minus two standard deviation level.

The Monte-Carlo results for this experiment are displayed in Figure 15 where the top two curves of (a) correspond to the individual \bar{P}_d statistics for the two anomalies and the lowest of the three curves is a plot of \bar{P}_f . Here we see that both structures are quite easily detected with a \bar{P}_d of well over 90% even at the low ABR of one. As is expected, removing the single-anomaly assumption causes the algorithm to retain a greater number of candidate structures (including the true anomalies) thereby raising \bar{P}_f above that seen in Section 6.3.1.

In Figure 15(c) we plot the average number of GLRTs as a function of ABR. Note that at

(a) Anomaly in fractal background
(ABR=1.5)

(b) Reconstruction of conductivity in
(a) using LLSE

(c) Reconstruction of conductivity
in (a) using (34)

Figure 13: Comparison of reconstructed conductivity profile using the LLSE of [40] and an estimate based upon the output of the scale-recursive anomaly detection algorithm. The true conductivity is shown in (a) and contains a single anomaly near the center of the region. The LLSE is shown in (b) and the estimate obtained from (34) is illustrated in (c). Here we see that the use of the information from the detection algorithm allows for the successful localization of the anomaly in space and scale without sacrificing our ability to resolve the fractal features of the conductivity profile in (a). Additionally, the GLRT procedure results in an accurate estimate of the anomaly's amplitude.

worst the complexity of this algorithm is still well below the complexity of the single-anomaly exhaustive search algorithm and only about 30% greater than the complexity of the single-anomaly scale-recursive algorithm. Thus, despite the fact that the multiple anomaly problem is, from a combinatorial viewpoint, significantly more complex than the single anomaly case, we see that the scale-recursive localization method represents a highly efficient and accurate means of localizing an unknown number of structures in the region of interest.

In Figure 16, we compare the full reconstruction results obtained from the LLSE to those where (34) is used to estimate the underlying conductivity for one run of the Monte-Carlo at an ABR of

Figure 14: Two-region anomaly structure

1.5. From Figure 16(b) we see that the LLSE is successful in reconstructing the structure on the left; however, the lower amplitude/more pixel anomaly is almost completely undetected. Figure 16(c) indicates that the incorporation of the information from the anomaly detection algorithm significantly improves the localization in space as well as scale of both anomaly structures, especially the rightmost. Finally, the anomaly amplitudes are better estimated using the GLRT method.

7 Conclusion and Future Work

In this paper, we have presented a framework based upon techniques from the areas of multiscale modeling, wavelet transforms, and statistical decision and estimation theory for addressing a variety of issues arising in anomaly detection problems. Beginning with a linear model relating the data and the quantity to be reconstructed, we use the wavelet transform to take the problem from physical space to scale space where computational complexity is reduced for a wide variety of problems [1, 4, 41] and where we are able to take advantage of the rich and useful class of models recently developed for describing the structure of the medium in the absence of anomalous activity [21, 35, 47, 50]. The problems of characterizing the number, positions, and magnitudes of anomaly structures was formulated using the tools of statistical decision theory. To understand how the physics of the problem and the constraints on the geometry of the data collection process affect our ability to isolate anomalous regions, we defined and explored the issues of anomaly detectability and distinguishability. This analysis led to the development of a scale-recursive algorithm employing a sequence of Generalized Likelihood Ratio Tests for extracting anomaly information from data.

This work was presented in the context of a linearized inverse scattering problem arising in geophysical prospecting. The same scattering model is encountered in a variety of other fields where some form of energy is used to probe a lossy medium [18–20, 22, 29, 31]. More generally, the analysis and algorithmic methods developed in this work require only a measurements model of the form in (2) and are thus relevant for any linear inverse problem (eg. computed tomography) in which anomaly characterization is of interest.

An important extension of the work presented here is in development of algorithms and analysis

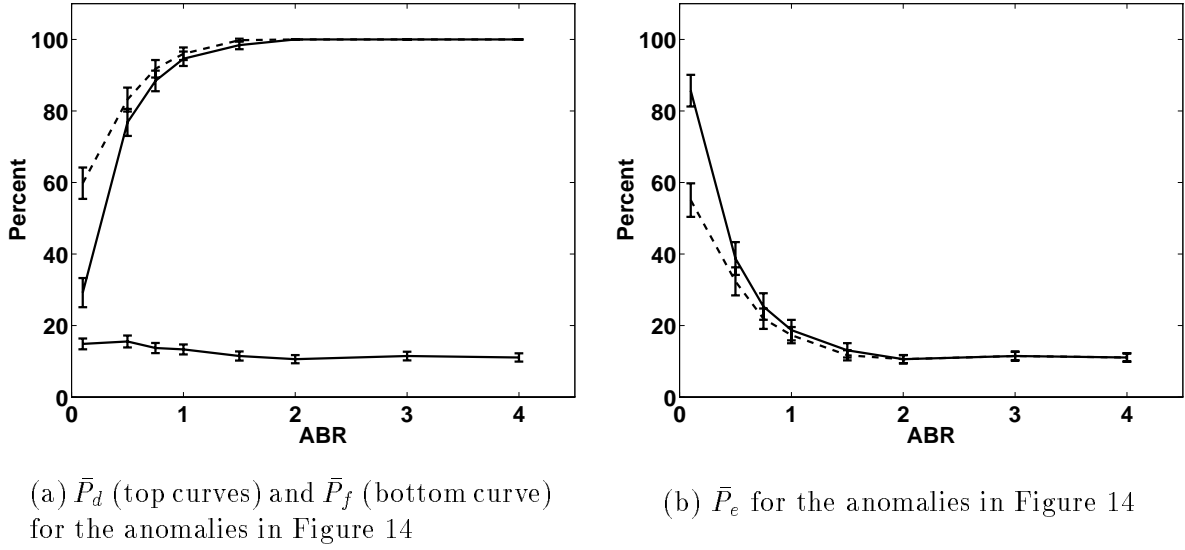

Figure 15: Performance curves obtained after 500 Monte-Carlo iterations of scale-recursive detection algorithm for the anomalies in Figure 14. Solid lines in (a) and (b) are detection and error probabilities for the upper left anomaly while dashed lines are for lower right anomaly. The error bars are drawn at the plus/minus two standard deviation level. In (c), the computational complexity associated with this scenario is shown by the solid line. For comparison, the dashed line is the complexity associated with the single anomaly exhaustive search.

methods for detecting anomaly structures using the *nonlinear* physics governing the relationship between the conductivity and the observed scattered electric field. The primary difficulty here is maintaining or improving the detection/false-alarm performance of the current method while retaining the low computation complexity in an algorithm based upon a significantly more complex scattering model. In [38] we present preliminary results for one form of a scale-recursive anomaly

Figure 16: Comparison of reconstructed conductivity profile using the LLSE of [40] and an estimate based upon the output of the scale-recursive anomaly detection algorithm. The true conductivity is shown in (a) and contains a two anomalies. The LLSE is shown in (b) and the estimate obtained from (34) is illustrated in (c). Here we see that the use of the detection information allows for the successful localization of both anomaly structures and offers a significant improvement over the LLSE in localizing the anomaly in the lower right.

characterization algorithm using the computationally efficient, nonlinear Extended Born Approximation [48]. Further work remains in the exploration of detectability and distinguishability in the nonlinear context and the extension of this approach to higher frequency (eg. microwave) problems.

Another avenue of research is in the use of alternate methods for progressively dividing the region of interest. The problem of anomaly detection is similar to that of image segmentation in that the goal of both is to partition a two-dimensional grid of pixels into disjoint regions. The primary difference between these two problems is the data. In the segmentation case the data are the pixels in the image whereas we wish to do the anomaly localization given the significantly less informative observations of scattered radiation. For the segmentation problem, significant work has been performed in the use of hierarchical methods for performing this decomposition. For example,

segmentation techniques have been developed where (a) small structures are merged into larger regions [36, 42] and (b) both splitting as well as merging operations are used in the segmentation process [28]. Examining the utility of merge- and split/merge-algorithms for the anomaly detection problem would be of considerable interest especially as a means of overcoming the difficulties of detecting small-scale structures using large scale hypotheses.

Abstract

In this paper we present an algorithm for the detection, localization, and characterization of anomalous structures in an overall region of interest given observations of scattered electromagnetic fields obtained along the boundary of the region. Such anomaly detection problems are encountered in applications including medical imaging, radar signal processing, and geophysical exploration. The techniques developed in this work are based on a non-linear scattering model relating the anomalous structures to the observed data. A sequence of M-ary hypothesis test are employed first to localize anomalous behavior to large areas and then to refine these initial estimates to better characterize the true target structures. We introduce a method for the incorporation of prior information into the processing which reflects constraints relevant directly to the anomaly detection problem such as the number, shapes, and sizes of anomalies present in the region. The algorithm is demonstrated using a low-frequency, inverse conductivity problem found in geophysical applications.

1 Introduction

A common problem arising in a variety of application areas is the non-invasive detection, localization, and characterization of anomalous areas in an overall region of interest given observations of scattered acoustic or electromagnetic radiation collected along a portion of the region's boundary [9, 15]. For example, tumor detection in otherwise healthy tissue arises frequently in many areas of medical signal processing [1]. In geophysical exploration, particularly low values of electrical conductivity in a region of the earth provide one indication as to the presence of oil [18]. Finally, there has been significant interest recently in the use of ground penetrating radar for the detection of buried objects such as land mines and metallic drums containing hazardous waste [14].

Typical methods for solving this *anomaly detection* problem proceed by first forming an image of distribution of a particular physical quantity (eg. sound speed or electrical permittivity) internal to the medium and subsequently post-processing the reconstructed profile to locate and classify anomalous areas [9, 15]. The problem of image formation from scattered field measurements (also known as the inverse scattering problem) presents a collection of difficulties which makes this image-then-detect approach rather unattractive. First, because the reconstructions are obtained typically over a fine scale grid of pixels, these problems are computationally intensive. The complexity of many practically interesting problems is further increased by the non-linear relationship between the physical parameter of interest and the observed scattered fields. The resulting imaging algorithms require the solution of a large-scale, non-convex, non-linear optimization problem [18].

Additional problems arise from the fact that one often is restricted to probing the medium with sources operating at only a few frequencies and observing the scattered fields over a limited portion of the region's periphery. As discussed in [11, 13] under these circumstances the imaging problem is highly ill-posed in that the information content in the the data does not support a stable fine-scale reconstruction of a pixelated representation of the physical parameter. Commonly, this problem

of ill-posedness is solved through the use of a regularization scheme which enforces a degree of smoothness in the reconstruction [10]. The use of such a regularizer for anomaly characterization serves to *increase* the difficulty of detection and identification after image formation. Typical targets represent regions where the medium's structure is locally *not* smooth. Imaging with a smoothness regularizer results in a low-pass image in which these distinguishing anomaly characteristics are softened thereby increasing the difficulty of subsequent detection and identification.

Over the past decade, significant research has been performed on the detection of anomalies directly from scattered field data. Rather than solving a large, ill-posed imaging problem, these techniques employ statistical signal processing methods to extract from the data a relatively small number of geometric parameters describing the distribution of anomalous structures. In [15], Rossi and Willsky considered the use of estimation-theoretic analysis and algorithmic methods for determining the location of a single object of known size and structure given noisy and sparse computed tomography (CT) measurements. Devaney and co-workers [3, 17] extended these results to diffraction tomography (DT) and exact scattering applications. In [2], Bressler, Fessler and Macovski presented an algorithm for determining the locations and geometric structures of an unknown number of anomalies based on CT measurements. A similar problem is considered in [16, 20], where the authors were concerned with the detection of an unknown number of circular objects of unknown radii given noisy CT observations. The iterative algorithms in [16, 20] began by identifying a large collection of likely targets with subsequent steps (a) pruning away structures which were deemed unlikely to be actual objects (b) refining the estimates of the radii and locations for the remaining objects.

A decision-theoretic, multiscale algorithm based on a sequence of M-ary, hypothesis tests was presented and analyzed in [11] for the characterization of an unknown number of anomalous regions of unknown size, shape and amplitude for problem in which a linear model related the anomalies to

the measurements. The approach in [11] began by identifying a small number of large sized regions in which anomalies were likely to exist. Subsequent processing steps refined these estimates and provided for the re-partitioning of each coarse scale region to account for the existence of multiple structures. The application of interest was a diffraction tomography problem arising in geophysical exploration.

In this paper, the problem of detecting and localizing an unknown number of anomalous areas is addressed for problems where linear scattering models are not valid so that the full, nonlinear physics must be incorporated into the processing. As in [11], the fundamental idea behind the approach presented here is the use of a sequence of hypothesis tests which begin by localizing anomalous behavior to a few, large sized areas and subsequently “zoom in” to better localize the true target structures. It should be noted that the spatial subdivision process considered here is quite different from that in [11]. In addition to the use of a non-linear scattering model, here we introduce a decision-theoretic regularization method which allows for the inclusion of prior information specifically tailored to the anomaly detection problem. Expectations regarding the number, sizes and shapes of anomalous areas are easily and naturally incorporated into the hypothesis testing process. While we do not examine the issue extensively in this work, the anomaly detection algorithm has a structure making it well tailored for a computationally efficient, parallel implementation. As in [11], we concentrate on a low-frequency geophysical inverse conductivity problem.

In Section 2 of this paper the scattering model and problem of interest are presented. An overview of the relevant detection methods is provided in Section 3. The multiscale anomaly detection algorithm is described in Section 4 and examples provided in Section 5. Section 6 is devoted to conclusions.

2 Problem Formulation

2.1 The Scattering Model

We consider a two-dimensional inverse conductivity problem illustrated in Fig. 1 where there exist a set of electromagnetic line-sources oriented perpendicularly to the page emitting time-harmonic waves into a lossy medium. The medium is characterized by the free space values for electric permittivity, ϵ_0 , and magnetic permeability, μ_0 and a conductivity profile modeled as the sum of a constant background, g_0 , and a collection of anomalies described by the function $g(\mathbf{r})$. The goal of the problem is to characterize $g(\mathbf{r})$ from noisy, pointwise observations of the component of the scattered electric field oriented perpendicularly to the page. These measurements are obtained along receiver arrays positioned on the vertical edges of A from K scattering experiments. Each experiment produces a vector of measurements, \mathbf{y}_i , comprised of the in-phase and quadrature components of the scattered field obtained over a single receiver array due to energy put into the medium from one of the sources operating at a frequency, $f_i = \omega_i/2\pi$.

As discussed in [18], the relationship between $g(\mathbf{r})$ and the j th element of \mathbf{y}_i ; that is, the measured scattered field at position \mathbf{r}_j is

$$y_i(\mathbf{r}_j) = \imath\omega_i\mu_0 \int_A G_i(\mathbf{r}_j, \mathbf{r}') E_i(\mathbf{r}') g(\mathbf{r}') d\mathbf{r}' + n_i(\mathbf{r}_j) \quad (1)$$

where $n_i(\mathbf{r}_j)$ represents additive noise, $G_i(\mathbf{r}, \mathbf{r}')$ is the Green's function for the problem and $E_i(\mathbf{r})$ is the component of the total electric field perpendicular to the page. From [18], $E_i(\mathbf{r})$ satisfies

$$E_i(\mathbf{r}) = \bar{E}_i(\mathbf{r}) + \imath\omega_i\mu_0 \int_A G_i(\mathbf{r}, \mathbf{r}') g(\mathbf{r}') E_i(\mathbf{r}') d\mathbf{r}' \quad (2)$$

with $\bar{E}_i(\mathbf{r}) = I_i \imath\omega_i\mu_0 G_i(\mathbf{r}, \mathbf{r}_i)$ the background field generated by a line source with current density I_i positioned at \mathbf{r}_i . Finally $G_i(\mathbf{r}, \mathbf{r}') = \imath/4H_0^{(1)}(k_{i,0}|\mathbf{r} - \mathbf{r}'|)$ is the Green's function for this problem with $k_{i,0}^2 = \omega_i^2\mu_0(\epsilon_0 + \imath g_0/\omega_i)$ and $H_0^{(1)}(z)$ the zeroth order Hankel function of the first kind.

A discrete representations of (1) is obtained using the method of moments (MOM) [8] where $g(\mathbf{r})$ and $E_i(\mathbf{r})$ are expanded in pulse bases (i.e. zeroth order splines). A Galerkin scheme is employed

to discretize (2) using the same pulse bases. Upon discretization, (1) and (2) reduce to

$$\mathbf{y}_i = \mathbf{G}_{i,s} \mathcal{D}(\mathbf{E}_i) \mathbf{g} + \mathbf{n}_i \quad (3a)$$

$$\mathbf{E}_i = \bar{\mathbf{E}}_i + \mathbf{G}_i \mathcal{D}(\mathbf{g}) \mathbf{E}_i \quad (3b)$$

where \mathbf{g} is a lexicographically ordered vector of expansion coefficients for $g(\mathbf{r})$, \mathbf{E}_i (resp. $\bar{\mathbf{E}}_i$) is a vector of coefficients for $E_i(\mathbf{r})$ (resp. $\bar{E}_i(\mathbf{r})$), $\mathbf{G}_{i,s}$ (resp. \mathbf{G}_i) is a matrix representation of the integral kernel in (1) (resp. (2)), and $\mathcal{D}(\mathbf{x})$ is the diagonal matrix whose (i, i) th element is the i th component of the vector \mathbf{x} . Solving for \mathbf{E}_i in (3b) and substituting the result in (3a) gives

$$\mathbf{y}_i = \mathbf{G}_{i,s} \mathcal{D} \left\{ [\mathbf{I} - \mathbf{G}_i \mathcal{D}(\mathbf{g})]^{-1} \bar{\mathbf{E}}_i \right\} \mathbf{g} + \mathbf{n}_i \equiv \mathbf{h}_i(\mathbf{g}) + \mathbf{n}_i. \quad (4)$$

In this paper, \mathbf{n}_i is taken to be additive, white Gaussian noise uncorrelated from one observation vector to the next. Thus, $\mathbf{n}_i \sim \mathcal{N}(\mathbf{0}, r_i \mathbf{I})$ and $E[\mathbf{n}_i \mathbf{n}_j^T] = r_i \mathbf{I} \delta(i - j)$ where \mathbf{I} is an appropriately sized identity matrix and $\delta(n)$ is the Kronecker delta.¹ Finally, we collect the data from the K scattering experiments into a single vector, \mathbf{y} so that the overall observation model is given by

$$\mathbf{y} = \mathbf{h}(\mathbf{g}) + \mathbf{n} \quad (5)$$

where $\mathbf{y}^T = [\mathbf{y}_1^T \ \mathbf{y}_2^T \ \dots \ \mathbf{y}_K^T]$, $\mathbf{h}(\mathbf{g})$ and \mathbf{n} are defined accordingly, and $\mathbf{n} \sim \mathcal{N}(\mathbf{0}, \mathbf{R})$ with $\mathbf{R} = \text{diag}(r_1 \mathbf{I}, r_2 \mathbf{I}, \dots, r_K \mathbf{I})$.

One difficulty with the use of (4) in the context of an inverse problem is that of computational complexity. A basic component of any inverse problem is the evaluation of \mathbf{y}_i for various values of \mathbf{g} . According to (4), each such evaluation requires the inversion of the large, dense matrix $\mathbf{I} - \mathbf{G}_i \mathcal{D}(\mathbf{g})$. In fact, for a discretization of A into an $N_g \times N_g$ array of pixels, this matrix is of size $N_g^2 \times N_g^2$. To overcome this computational burden, the algorithm discussed in Section 4 is implemented using the nonlinear, extended Born approximation (EBA) [6] to the true scattering model. That is, for all computations, $\mathbf{h}_i(\mathbf{g})$ is replaced by $\mathbf{h}_i^{EBA}(\mathbf{g})$ where a detailed discussion of $\mathbf{h}_i^{EBA}(\mathbf{g})$ may be found in [6, 13, 18]. Like the true scattering physics, the EBA is a nonlinear

¹The notation $\mathbf{x} \sim \mathcal{N}(\mathbf{m}, \mathbf{P})$ indicates that the random vector $M\mathbf{x}$ has a Gaussian probability distribution with mean \mathbf{m} and covariance matrix \mathbf{P} .

function of the conductivity. For the geophysical application of interest here, the EBA has been shown to provide a highly accurate approximation of $\mathbf{h}_i(\mathbf{g})$ even for conductivity profiles where the more common Born or Rytov linearized models are no longer valid [6, 18]. The principle advantage of the EBA is that the computational complexity of the approximation is a small fraction of that associated with the exact scattering model [18].

2.2 The Anomaly Model

Because the MOM discretization procedure pixelates A into an array of rectangular cells and because the algorithm in Section 4 performs anomaly localization through a process of spatial subdivision, we are lead naturally to consider a representation for \mathbf{g} in which anomalous regions are defined to be superpositions of rectangular subsets of A . Referring to Fig. 2, the structure of the i th anomaly in A is defined by its magnitude, its size, and its location in A . Mathematically, the form for the anomalous behavior of the conductivity over the region A is

$$\mathbf{g} = \sum_{j=1}^{N_a} \mathbf{b}_j a_j = \mathbf{B}\mathbf{a}. \quad (6)$$

Here, N_a is the number of anomalous regions located in A , a_j is a scalar defining the magnitude of each anomaly, and \mathbf{b}_j represents the discrete indicator function over the j th rectangular region. In (6), the column vector \mathbf{a} represents the collection of anomaly amplitude coefficients while \mathbf{B} is the matrix whose j th column is the lexicographically ordered form of \mathbf{b}_j . We note that the algorithm in Section 4 is not dependent upon the assumption of rectangular anomalies; rather structures with arbitrary shapes and orientations can be employed in principle through the appropriate specification of the matrix \mathbf{B} . Finally, the anomaly detection problem may now be stated in the following manner: Given the data and the noise statistics, determine the structure of the matrix \mathbf{B} and the vector \mathbf{a} , i.e. find the number, locations, sizes, and the amplitudes of the anomalous regions in A .

3 M-Ary Hypothesis Testing

The anomaly detection algorithm to be presented and analyzed in Sections 4 and 5 is based on a sequence of M-ary hypothesis tests [19] in which each hypothesis corresponds to a particular anomaly distribution in A . That is, the m th hypothesis for one such test takes the form

$$H_m : \quad \mathbf{g} = \mathbf{B}_m \mathbf{a}_m \quad (7)$$

for $m = 0, 1, \dots, M - 1$. In (7) \mathbf{B}_m describes the geometric characteristics of the hypothesized anomaly configuration and \mathbf{a}_m is the associated amplitude vector.

Given a data vector, the hypothesis test itself may be viewed as a rule for selecting the “best” anomaly configuration from among the M possible choices. In this paper, the following maximum *a posteriori* (MAP) procedure is employed

$$\text{Choose } H_m \text{ with } m = \arg \max_j \log [p_{\mathbf{y}|H_j}(\mathbf{Y}|H_j)] + \log(p_j) \quad (8)$$

where $p_{\mathbf{y}|H_j}(\mathbf{Y}|H_j)$ is the probability density function for the data under H_j and p_j represents the prior probability that H_j is in fact true. The Gaussian model for \mathbf{n} allows (8) to be written as

$$\begin{aligned} \text{Choose } H_m \text{ with } m &= \arg \min_j \frac{1}{2} \|\mathbf{y} - \mathbf{h}(\mathbf{B}_j \mathbf{a}_j)\|_{\mathbf{R}^{-1}}^2 + \pi_j \\ &\equiv \arg \min_j \ell_j(\mathbf{y}) + \pi_j \end{aligned} \quad (9)$$

where $\|\mathbf{x}\|_{\mathbf{A}} \equiv \mathbf{x}^T \mathbf{A} \mathbf{x}$ and $\pi_j = -\log(p_j)$.

For the anomaly detection algorithm in Section 4, the amplitude vectors, \mathbf{a}_m , are assumed to be deterministic, but unknown quantities. Thus, a generalized hypothesis test is employed in which \mathbf{a}_m in (7) is replaced by the following estimate of \mathbf{a}_m given the data

$$\hat{\mathbf{a}}_m = \arg \min_{\mathbf{a}_m > -g_0} \frac{1}{2} \|\mathbf{y} - \mathbf{h}(\mathbf{B}_m \mathbf{a}_m)\|_{\mathbf{R}^{-1}}^2 + \alpha^2 \|\mathbf{a}_m\|. \quad (10)$$

The notation $\mathbf{a}_m > -g_0$ implies that each element of the vector \mathbf{a}_m is greater than the negative of the background conductivity and is required to ensure that the overall conductivity in region A , is greater than zero [18]. As in [11], (10) represents a regularized, maximum likelihood estimate of the amplitude vector where the second term is used to offset any ill-posedness in the estimation problem.

The solution to this constrained non-linear, least squares optimization problem is obtained using a Gauss-Newton algorithm [4] modified to account for the bound constraint in \mathbf{a}_m .

The evaluation of the each likelihood statistic, $\ell_m(\mathbf{y})$, requires the solution of a non-linear optimization problem; however, the dimension of each problem is equal to the number of anomalies associated with H_m which is typically far less than the number degrees of freedom found in imaging application [13, 18]. Thus, the computational burden of each optimization problem is quite small relative to an image-then-detect approach. For all examples presented in Section 5, the Gauss-Newton method typically converged in well under 10 iterations. Finally, while the hypothesis test does require the solution of many small optimization problems, each $\ell_m(\mathbf{y})$ may be evaluated independently so that complexity can in principle be kept low through a parallel implementation of the test.

4 The Anomaly Characterization Algorithm

Here we present a multiscale algorithm for the detection and characterization of an unknown number of anomalous areas in region A based on a sequence of MAP hypothesis tests. Two classes of tests are employed in this algorithm where each test takes as input the current estimate of the anomaly structures in the form of a geometry matrix, $\hat{\mathbf{B}}$, and an estimated amplitude vector $\hat{\mathbf{a}}$. The overall algorithm is a sequence of *localization hypothesis tests* which “zoom in” on the true anomalous regions coupled with *pruning tests* designed to eliminate false alarms thereby controlling the amount of work required to identify true anomalous structures.

In Fig. 7, a pseudo-code listing of the algorithm is displayed. The algorithm begins with a single localization test in which anomalous activity is identified in a collection of relatively large size areas in region A . After this coarse-scale detection procedure, the basic processing step is comprised of a single localization-type test followed by a sequence of one or more pruning tests.

The algorithm terminates when successive null hypotheses are chosen for both a localization test and then a pruning test; that is, when it is determined that no further subdivision is warranted and no structures should be removed from the current configuration. Essentially, this approach grows a tree of hypothesized anomaly configurations where the root of the tree is a single anomaly over all of region A and the leaves are either new anomaly structures or increasingly localized estimates of current anomalies.

A key feature of this procedure is the specification of the non-negative penalty terms, π_j , in (9) (or equivalently the prior probabilities $p_j = e^{-\pi_j}$) to control the manner in which the tree is both grown (i.e. new anomalies are added or old ones further refined) as well as pruned (i.e. structures are removed from processing.) For example, hypotheses may be penalized to a greater or lesser degree depending on features such as the number of anomalies associated with \mathbf{B}_m , the spatial distribution of these structures, or geometric characteristics such as area or shape. Thus, in their ability to mathematically capture prior expectations and constraints, the π_j play the same role in the hypothesis testing framework as that of a smoothness regularizer in a more traditional imaging-type problem [10]. In the anomaly detection context, the property of smoothness is not of concern, but rather geometric characteristics of the anomaly distribution are the natural features for which prior models are required. The remainder of this section is devoted to a description of both classes of hypothesis tests.

4.1 The Localization Hypothesis Test

Given an estimated configuration of anomalies in region A , the spatial refinement hypothesis test used here indicates either that no further localization is deemed necessary or further refinement is warranted in which case only a single structure in the current anomaly collection is further subdivided. Formally, suppose that N regions in A have been identified as containing anomalies so that $\hat{\mathbf{B}}$ contains N columns, $\hat{\mathbf{b}}_j$, $j = 1, 2, \dots, N$. Localization to smaller regions of A is obtained

through the use of a test with $8N + 1$ hypotheses. The first hypothesis corresponds to retaining the current $\hat{\mathbf{B}}$ indicating that no further localization is warranted. Under the next 8 hypotheses, the first column of $\hat{\mathbf{B}}$ is replaced by one or more columns corresponding to anomalies with support over a subset of the region corresponding to $\hat{\mathbf{b}}_1$. This same construction is repeated with $\hat{\mathbf{b}}_1$ replaced by $\hat{\mathbf{b}}_j$ for $j = 2, 3, \dots, N$. Thus, the non-null hypotheses correspond to $8N$ ways in which anomalies can be better localized by perturbing only one of the N elements of $\hat{\mathbf{B}}$.

In Fig. 4, the decompositions of $\hat{\mathbf{b}}_j$ of interest in this paper are displayed. The first six choices correspond to the true anomaly being located in the top, bottom, left, right, vertical middle, and horizontal middle of the region given by $\hat{\mathbf{b}}_j$. The last two decompositions allow for the presence of two anomalies in $\hat{\mathbf{b}}_j$: one in the top and one in the bottom or one in the left and one in the right. By choosing one of these last two hypotheses, we are able to identify multiple structures in A .

As discussed in Section 3, we associate with each hypothesis a matrix, \mathbf{B}_m for $m = 0, 1, \dots, 8N$ where $\mathbf{B}_0 = \hat{\mathbf{B}}$ and for $m > 0$, \mathbf{B}_m is equal to $\hat{\mathbf{B}}$ with one column replaced either by a single column, as is the case for the first six hypotheses in Fig. 4, or two column vectors for the last two hypotheses. In either case, we define $\tilde{\mathbf{b}}_m$ to be the column(s) in \mathbf{B}_m different from those in $\hat{\mathbf{B}}$.

In addition to specifying \mathbf{B}_m , the MAP test requires that the penalty terms π_m , also be specified. For the cases where $\tilde{\mathbf{b}}_m$ contains one column, we begin by defining a collection of quantities $\tilde{\pi}_m$ as

$$\tilde{\pi}_0 = 10^\sigma f_0 \left(\max_k |\hat{\mathbf{b}}_k| \right) \quad (11)$$

and for $m > 0$

$$\tilde{\pi}_m = \begin{cases} +\infty & |\tilde{\mathbf{b}}_m| < 4 \text{ or } \epsilon(\tilde{\mathbf{b}}_m) > 4 \\ 10^\sigma \text{card}(\tilde{\mathbf{b}}_m) f_1(|\tilde{\mathbf{b}}_m|) & \text{otherwise} \end{cases} \quad (12)$$

where $|\tilde{\mathbf{b}}_m|$ is the number of non-zero pixels in $\tilde{\mathbf{b}}_m$; $\epsilon(\tilde{\mathbf{b}}_m)$ is the ratio of the length of longer to the shorter side of the anomaly and provides a measure of the eccentricity of the structure; $\text{card}(\tilde{\mathbf{b}}_m)$ is the number of columns in $\tilde{\mathbf{b}}_m$ (in this case one); and $f_0(|\mathbf{b}_m|)$ and $f_1(|\mathbf{b}_m|)$ are plotted in Fig. 5.

When $\tilde{\mathbf{b}}_m$ contains two columns, the number of nonzero pixels in each column are equal and the geometric structures of the underlying anomalies are the same (only their positions in A differ), so that there is no ambiguity in assuming that $|\tilde{\mathbf{b}}_m|$ and $\epsilon(\tilde{\mathbf{b}}_m)$ refer to the first column in these cases.

Finally, π_m are obtained from $\tilde{\pi}_m$ via

$$\pi_m = \tilde{\pi}_m - \log \left(\sum_{k=0}^{8N} \tilde{\pi}_k \right) \quad (13)$$

thereby ensuring that $\sum_{m=0}^{8N} p_m = \sum_{m=0}^{8N} e^{-\pi_m} = 1$.

The parameter σ in (11) and (12) determines the overall magnitude of the penalty terms in the hypothesis test. Thus, selection of σ is analogous to the determination of the regularization parameter in many imaging type inverse problems [5, 7]. For σ too small the prior information will have negligible impact on the hypothesis test while an excessively large value of σ negates the influence of the data. In this paper, σ is chosen using the following somewhat *ad hoc* approach

$$\sigma = \left\lfloor \log_{10} \frac{1}{2} \|\mathbf{y} - \mathbf{h}(\mathbf{1}\hat{\mathbf{a}})\|_{\mathbf{R}^{-1}}^2 \right\rfloor - 1 \quad (14)$$

where $\mathbf{1}$ is the indicator function over all of region A , $\hat{\mathbf{a}}$ is the ML amplitude for an anomaly with this structure, and $\lfloor x \rfloor$ is the greatest integer less than or equal to x . Thus, σ is selected so that the largest of the $\tilde{\pi}_m$ is roughly an order of magnitude less than the size of the covariance weighted error between the data and the initial estimated anomaly structure used in the algorithm.

Fig. 5 and eqs. (11) and (12) demonstrate that the penalty terms are chosen to reflect prior expectations regarding the sizes, shapes and number of anomalies in region A . The structure of $f_0(|\mathbf{b}_m|)$ indicates that as the size of the largest structure in $\hat{\mathbf{B}}$ increases, the penalty for *not* performing a decomposition increases thereby encouraging the decomposition of larger structures. The first condition in (12) is used to ensure that no structures are identified if they contain few than four pixels or if they are too long and fat or tall and thin. That is, we require anomalies to have a minimum area and not be excessively elongated. The second condition in (12) and the form of $f_1(|\mathbf{b}_m|)$ indicate that the penalty increases as the number of columns in $\tilde{\mathbf{b}}_m$ increases and the size

of the structures decreases. Thus, the prior expectations serve to prevent the identification of many small anomalies in region A . Clearly, depending on the application, other prior modeling choices are both possible and interesting. The selection made here is useful for the inverse conductivity problem under consideration and provides a successful demonstration of the utility of prior modeling in an hypothesis testing framework for capturing information not commonly accessible to traditional regularization schemes.

4.2 The Pruning-Type Hypothesis Test

The second class of hypothesis tests used here are designed to eliminate from consideration previously identified regions which are unlikely to actually contain anomalies. Given an estimated geometry matrix $\hat{\mathbf{B}}$ with N columns, the anomaly removal hypothesis test consists of $N + 1$ hypotheses with $\mathbf{B}_0 = \hat{\mathbf{B}}$ and for $m = 1, 2, \dots, N$, \mathbf{B}_m equals $\hat{\mathbf{B}}$ with the m th column removed. Thus, at most one structure is eliminated per hypothesis test.

With $\hat{\mathbf{b}}_m$ the column of $\hat{\mathbf{B}}$ removed for the m th test, $\tilde{\pi}_m$ for the pruning-type hypothesis test is

$$\tilde{\pi}_m = \begin{cases} 10^\sigma f_2(N) & m = 0 \\ 10^\sigma f_3(|\hat{\mathbf{b}}_m|) & m = 1, 2, \dots, N \end{cases} \quad (15)$$

where $f_2(N)$ and $f_3(|\hat{\mathbf{b}}_m|)$ are shown in Figs. 5(a) and (b), σ is chosen as in (14), and π_m are obtained from $\tilde{\pi}_m$ using (13). As seen in Fig. 5, the form of $f_2(N)$ indicates an increasing penalty as the number of estimated structures rises. Also, Fig. 5(a) shows that $\tilde{\pi}_m$ increases as the size of the anomaly being removed from consideration rises thereby penalizing against the premature removal of large-scale structures.

4.3 Initial Localization

For the algorithm presented in this section to detect and localize relatively small anomalies, during the initial processing stages the correct large scale structures which overlap the true, smaller sized anomalies must be chosen for further processing. In [11], this coarse-scale localization issue

was analyzed in depth for a decision-theoretic anomaly detection algorithm applied to a scattering problem identical to the one considered here but using a linearized model rather than the non-linear model of Section 2. There, it was shown that the probability of a coarse scale miss was unacceptably high. In that case, performance was improved simply by retaining a greater number of coarse-scale regions for further decomposition than would otherwise be the case.

With these results in mind, in this paper we address the problem of coarse scale localization by modifying the hypothesis set used in the first localization test. Specifically, we supplement the decompositions of region A presented in Fig. 4 with those shown in Fig. 6 making for a 15-ary initial hypothesis test rather than the 8-ary test described in Section 4.1. Additionally, after performing this expanded localization-type test, we retain for further processing *all other* areas in region A not part of the chosen decomposition. For example, if the selection labeled “Horizontal middle two” is chosen from Fig. 6, then *four* anomalies are identified for further processing: the two square structures in the middle of region A as well as the two long, narrow regions at the top and bottom. While alternate means may be developed for addressing this issue of coarse scale localization, the method described here balances the conflicting requirements of an exhaustive, fine scale search over region A for likely targets and the desire to limit the computational overhead of the algorithm.

5 Examples

We consider the problem of characterizing conductivity anomalies given data from the scattering experiments described in Table 1. Region A is $100\text{ m} \times 100\text{ m}$ and discretized into a 16×16 array of pixels. The background conductivity is 0.1 S/m . The source frequencies are 100 Hz (used in a cross-well configuration) as well as 1 and 10 kHz (used to obtain information near the left edge of A). Both receiver arrays consist of 32 equally spaced elements extending from $z = -0.05\text{ m}$ to $z = 100.05\text{ m}$. The left array is located at $x = -0.05\text{ m}$ and the right at $x = 100.05\text{ m}$. The six

sources are located along the line $x = -0.05$ m equally spaced from $z = 0.05$ m to $z = 99.95$ m.

The anomalies in all experiments are taken to have amplitudes of 1 S/m representing a 10:1 contrast against the background conductivity. Under conditions such as these, it is well known that the Born and Rytov linearizations of the scattering physics fail to hold thereby necessitating the use of a more complete, nonlinear scattering model. While the detection algorithm is based on the extended Born approximation (EBA) described in Section 2.1, the data vectors for all simulations are generated using the exact scattering model in (3a) and (3b).

The performance of the anomaly detection algorithm is assessed using a collection of different anomaly configurations under a variety of signal to noise conditions. For the model $\mathbf{y}_i = \mathbf{h}_i(\mathbf{g}) + \mathbf{n}_i$ with $\mathbf{y}_i \in \mathbb{R}^{N_i}$ and $\mathbf{n}_i \sim \mathcal{N}(0, r_i^2 \mathbf{I})$, the signal-to-noise ratio (SNR) in decibels is defined as

$$SNR_i = 10 \log_{10} \left\{ \frac{[\mathbf{h}_i(\mathbf{g})]^T [\mathbf{h}_i(\mathbf{g})]}{N_i r_i^2} \right\}. \quad (16)$$

For each anomaly configuration performance is examined at SNRs of 40, 20, 10, and 0 dB. Given an anomaly and SNR combination, the detection algorithm is executed for 10 independent realizations of the measurement noise process with the results of these runs forming the basis for our evaluation.

The information for each anomaly configuration is analyzed both quantitatively as well as qualitatively. From a quantitative perspective, we are concerned with the detection and false alarm probabilities associated with the algorithm. An anomaly is classified as having been detected if the $\hat{\mathbf{B}}$ matrix produced at the last stage of the algorithm contains at least one structure which overlaps the true anomaly structure. All structures in the final $\hat{\mathbf{B}}$ matrix not corresponding to detections are taken to false alarms. The statistic of interest here is the rate of false alarms per unit area defined as number of falsely identified pixels divided the total number of pixel in A . Finally, the results of the anomaly detection algorithm are compared against those of an imaging-type inverse scattering algorithm described in [13]. This reconstruction procedure requires the solution of a nonlinear least squares problem. The method of [13] is based on a form of the Levenburg-Marquardt algorithm

and makes use of the EBA to lower the algorithm's computational complexity.

While it is not the objective of this paper to provide an exhaustive analysis of the computational complexity of the anomaly detection algorithm, this approach is generally more efficient than the imaging technique of [13]. All algorithms in this paper have been implemented in Matlab and executed on a dual processor, SparcStation 20 with 64Mb of internal RAM. The time required for a single run of the anomaly detection algorithm varied from 4 to about 7 hours depending on the underlying anomaly configuration and the noise conditions. For the imaging algorithm, 50 iterations of the Levenburg-Marquardt technique were used to process each data set at which point the algorithm had converged to a minimum of the least-squares cost function. In contrast to the detection-based approach, the imaging algorithm required between 24 and 36 hours of processing.

5.1 Experiment I: A Single Anomaly

The first anomaly configuration of interest here is shown in Fig. 7(a) and consists of a single structure located near the middle of region *A*. As discussed in [11–13], for inverse problems of the type considered in this paper, the ability to resolve anomalous behavior is greatest near either vertical edge of region *A* where the sources and receivers are located. For locations in the middle of the region, it becomes increasingly difficult to detect structures or resolve fine scale detail in the conductivity profile. Finally, the structure in Fig. 7(a) is aligned on the underlying grid of 16×16 pixels in such a manner that it is not possible for a decomposition scheme based upon the hypotheses in Figs. 4 and 6 to produce an estimated anomaly which is *exactly* of the same shape as the truth. Thus, this example represents a particularly challenging anomaly configuration for the algorithm.

In Fig. 7(b), the detection and false alarm probabilities are displayed for this case where the error bars indicate plus and minus two standard deviations from the sample mean. For the 40, 20, and 10 dB SNR cases, the anomaly was detected 100% of the time. At 0 dB, the detection

rate drops to 80%; however for the two cases in which the target was missed, the output of the algorithm did include an estimated anomaly located directly above the true structure. Thus, the target essentially was localized for all runs at all SNRs. Finally, the false alarm rate is at most 5% or 12 falsely identified pixels out of the 256. Sample estimates of anomaly configuration at 40dB and 10 dB SNR are presented in Fig. 8(a)–(b). The dashed lines overlaying these images indicate the region of A occupied by the true structure. We note that at both SNRs, the anomaly is detected. At 40 dB, there is also a small amplitude, falsely identified structure while the 10 dB example is free of such false alarms.

In Fig. 9, we display intermediate results of the algorithm for one trial at 0 dB. In Fig. 9(a), the estimated anomaly structure is shown after the first location test. Here we see that the algorithm has chosen to examine the 4 quarters of region A . Even at this coarse processing stage the structure with the largest amplitude is the quarter in which the true anomaly resides. In Figs. 9(b)–(e), the identified anomaly configuration is shown after one quarter, one half, three quarters and all of the processing for this trial. It is evident that well before the algorithm has terminated, the true anomaly is rather well localized. While there do exist falsely identified structures in the left side of Fig. 9(e) their amplitudes are far smaller than that of correctly identified anomaly. Thus, post-processing the results of the anomaly detection algorithm to remove structures whose magnitudes are in some sense small would further lower the false alarm rate. Finally, in Fig. 9(f) the results of the imaging algorithm are displayed for the same data set used to generate Figs. 9(a)–(e). In this case, the imaging algorithm does indicate the existence of a structure in the correct location. However, the geometric and amplitude information in this image is inferior to that generated by the detection algorithm, and as noted previously, the generation of this image took significantly longer than that of Fig. 9(e).

5.2 Experiment II: Two anomalies close to the left edge

In Fig. 7(c), the second anomaly configuration of interest in this paper is presented. Here we are interested in recovering the composition of two structures both of which are located close to the left vertical edge of region A . As discussed in Section 5.1, previous work has demonstrated that anomalous behavior is most easily detected near the sources and receivers. Thus, the structures in Fig. 7(c) are meant to test the ability of the detection algorithm to successfully isolate multiple anomalies.

For all trials and at all SNRs, Fig. 7(c) indicates that both structures are detected with a false alarm rate again less than 5%. Sample estimates are displayed for trials at 40 dB and 10 dB SNR respectively in Fig. 8(c)–(d). The reconstruction at 40 dB is basically identical to the true structures both in terms of geometry as well as amplitude. For the 10 dB case, both structures are correctly identified with the geometry of the lower anomaly rotated relative to that of the true structure. Again, the amplitudes are close to the true values of 1 S/m. In Fig. 10(a)–(e), the results of the detection algorithm at various stages of processing are displayed for one trial at 0 dB SNR. After the opening localization test, the most likely region for further decomposition corresponds to a subset of A containing both structures. As the algorithm proceeds, this area is further decomposed to better localize the two individual structures. Like the previous example, the falsely identified regions at the end of the algorithm are also those with the smallest amplitudes. Finally, in Fig. 10(f), the results of the imaging algorithm are displayed. For this particular data set, the imaging approach provides a severely degraded representation of the bottom structure and entirely misses the top anomaly.

5.3 Experiment III: Two separated anomalies

The anomaly configuration for the last example considered in this paper is shown in Fig. 7(e). From the previous experiments, the anomaly located close to the left edge of A should be relatively

easy to detect while the second structure positioned closer to the right vertical edge should be less detectable. This intuition is born out by the curves in Fig. 7(f) which show that both structures were detected for all trials at SNRs of 10, 20 and 40 dB. At 0 dB SNR, the smaller structure was identified in all 10 trials which the larger one was detected in 8 out of the 10 experiments. As in the first example, for the two cases in which this structures was not detected there was an estimated anomaly whose support was directly adjacent to that of the true structure. Finally, the false alarm rate for this example is again below 5%.

Sample results of the algorithm at 40 and 10 dB SNR are displayed in Fig. 8(e)–(f) where it is seen that at both noise levels, the structures are well localized. The amplitude of of the smaller structure is quite close to 1 while that of the second structure is about 1.5 for the 40 dB case and 2 at 10 dB. In Fig. 11, the results of one experiment at 0 dB SNR are plotted. Unlike the previous two cases, at the opening stages of the algorithm, the anomaly with the largest amplitude is located in a region not containing one of the true structures. Nonetheless, in the final estimate, the smaller structure is exactly identified and one of the estimated anomalies fully overlaps the second, larger structure. In contrast to the results of the detection algorithm, the imaging results for this problem, shown in Fig. 11(f) demonstrate that only a severely blurred representation of the left anomaly is available with essentially no information present regarding the structure on the right of region A .

6 Conclusion

In this paper, we have developed and tested an algorithm for the detection, localization, and characterization of a collection of anomalous areas in an overall region of interest from observations of scattered radiation obtained along the region’s boundary. Our approach employs a full, non-linear measurement model relating the anomalous structures to the observed fields and thus provides a

method for solving the target detection problem in cases where more common models based on the Born or Rytov linearizations are not valid. The algorithm makes no assumption concerning the number of anomalies present in the region or the amplitudes of these structures. While the method presented in this paper is adapted to the detection anomalies of which are rectangular in shape, as discussed in Section 2.2 the rectangular assumption is not required.

The anomaly detection algorithm is structured as a sequential hypothesis testing procedure which begins by localizing anomalous behavior to relatively large areas in the overall region. Subsequent tests are used to spatially refine the coarse-scale regions and prune away structures which are deemed unlikely to contain anomalies. Finally, we have developed a decision-theoretic scheme for the easy incorporation of prior information directly relevant to the anomaly detection problem into the spatial subdivision process. A MAP hypothesis testing framework was used to capture expectations regarding issues such as the number, shapes, and sizes of structures in the region.

The algorithm has been tested on a low frequency inverse electrical conductivity problem arising in geophysical exploration. The results in Section 5 demonstrate that high detection and low false alarm rates are obtainable even in highly noisy environments where more conventional imaging-type reconstruction algorithms fail to produce useful results. The decision-theoretic detection algorithm considered in this paper was far more computationally efficient than the full scale imaging algorithm and has a structure making it well suited for implementation in a parallel or distributed processing environment where these computational gains would be significantly enhanced.

Abstract

We present a new application of the recursive T-matrix algorithm to calculate the scattered field from a single or multiple metallic cylinders of arbitrary shapes. Using the equivalence theorem each metallic object is replaced with small metallic cylinders along its perimeter, then scattered fields are calculated using the recursive T-matrix algorithm. Results are verified with those in the literature and analytical calculations.

Keywords: Scattering, recursive T-matrix algorithm

1 Introduction

The transition matrix (T-matrix) technique is known to be an efficient electromagnetic forward solver for scattering problems involving objects with simple shapes. Finite difference and method of moments (MoM) techniques both discretize the entire region of interest resulting in a large number of unknowns, whereas T-matrix methods replace this discretization with harmonic expansions of the fields thereby reducing the number of unknowns for numerous problems. Waterman [1] developed the T-matrix technique for single metallic or dielectric scatterers. Peterson et.al. [2] introduced an iterative algorithm which finds the scattering due to multiple scatterers. Recently Chew and co-workers have developed a number of fast, recursive T-matrix algorithms for determining the scattered fields in a variety of scenarios [3–9]. Among this work, in [4], problems involving electrically large dielectric objects are considered. By tessellating the objects into many small cylindrical sub-scatterers and using multipole expansions of the fields for each sub-scatterer the authors arrive at a highly efficient, T-matrix based algorithm for computing the scattered fields. In [7], Chew et.al. consider a scattering problem involving a group of metallic strips. Here the method of moments is used to compute the T-matrices for each, individual strip and the same recursion as in [6] is employed to solve the overall, multi-object scattering problem. In [8] the scattered field from an ogive shaped scatterer with metallic and dielectric parts is found using the recursive T-matrix algorithm. In that paper, as in [7], the metallic scatterer is decomposed into a collection of strips arrayed about the boundary and the T-matrices for the individual strips are found using the method of moments.

In this letter we consider an alternative sub-scatterer discretization for metallic objects from that in [7,8]. Instead of using metallic strips to model the perimeter of scatterers, we use metallic cylinders (similar to the concept in [4]) placed about the perimeter and employ the same recursive

algorithm given in [4] to calculate the scattered field. As a result, we obtained an accurate, efficient forward solver which does not require the use of method of moments to form the single scatterer T-matrices. Rather we obtained these quantities by using closed form, low order harmonic expansions associated with the small metallic cylinders. We apply this method to single electrically large metallic objects and verify the results with those in literature and analytical results. Additionally we demonstrate the usefulness of the method for the multi-object case by verifying against previously published results.

2 Recursive T-matrix Algorithm

The algorithms in [3,4,6,7,9] are order recursive methods for constructing the T-matrix for a multi-object scattering problem given the T-matrices for each individual object. The algorithm uses the basic principle of the single scatterer T-matrix formulas in that for each object, the scattered fields from others are assumed a part of a total incident field. The recursion starts with the T-matrices of individual scatterers, then one by one scatterers are incorporated into the equation and the T-matrices are updated until the final form of the T-matrix, including all multiple scattering effects, is obtained.

Formally, for L scatterers, the harmonic expansion of scattered field can be written as [4]:

$$\psi^{sc}(\underline{r}) = \sum_{i=1}^L \underline{\psi}^T(\underline{r}_i) \mathbf{T}_{i(L)} \beta_{i,0} \underline{a} \quad (1)$$

where $\mathbf{T}_{i(L)}$ is the T-matrix for i th object in the presence of L scatterers, \underline{a} is the coefficient vector used in the expansion of the incident plane wave in terms of cylindrical basis functions and $\beta_{i,0}$ is the translation matrix used to translate same type basis functions between reference coordinate systems. (The translation matrices $\beta_{i,0}$ contain Bessel functions and complex exponentials. For details about these matrices see [2,3].) Expansion of the scattered field in (1) is valid if all observation points

are outside the smallest circle enclosing all scatterers. Following Chew's derivation, the recursive construction of $\mathbf{T}_{i(L)}$ can be written as [4, eq.10-11] :

$$\mathbf{T}_{n+1(n+1)}\boldsymbol{\beta}_{n+1,0} = \left[\mathbf{I} - \mathbf{T}_{n+1(1)} \sum_{i=1}^n \boldsymbol{\alpha}_{n+1,i} \mathbf{T}_{i(n)} \boldsymbol{\beta}_{i,0} \boldsymbol{\alpha}_{0,n+1} \right]^{-1} \mathbf{T}_{n+1(1)} \left[\boldsymbol{\beta}_{n+1,0} + \sum_{i=1}^n \boldsymbol{\alpha}_{n+1,i} \mathbf{T}_{i(n)} \boldsymbol{\beta}_{i,0} \right] \quad (2)$$

and

$$\mathbf{T}_{i(n+1)}\boldsymbol{\beta}_{i,0} = \mathbf{T}_{i(n)}\boldsymbol{\beta}_{i,0} + \mathbf{T}_{i(n)}\boldsymbol{\beta}_{i,0} \boldsymbol{\alpha}_{0,n+1} \mathbf{T}_{n+1(n+1)}\boldsymbol{\beta}_{n+1,0} \quad (3)$$

where $n = 1, 2, \dots, L$, $i = 1, 2, \dots, n$ and $\boldsymbol{\alpha}_{n,i}$ is another translation matrix [3]. The recursion starts with the individual T-matrices, $\mathbf{T}_{i(1)}$, of the scatterers, i.e. the T-matrix of the i th scatterer when there are no other scatterers in the medium.

Theoretically the matrices $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, \mathbf{T} are of infinite dimension. The T-matrix algorithms truncate these matrices with finite values N and M such that the residual error is below the machine precision or acceptable levels. Here N represents the number of harmonics used to expand the fields at the scattering origin and M represents the number of harmonics used to expand the fields in the objects' local coordinate systems. Thus, the T-matrix is of size $M \times M$, $\boldsymbol{\beta}_{i,0}$ is of size $M \times N$ and $\boldsymbol{\alpha}_{i,n+1}$ is of size $M \times M$. It has been shown that computational complexity of (2)-(3) is $O(L^2 M^2 N)$ for L scatterers [4].

The contribution of this letter is to show that, based on the equivalence theorem, recursive T-matrix algorithms can be used to calculate the scattered fields from metallic objects by placing small metallic cylinders on their perimeter. Traditionally, the recursive T-matrix algorithm has been applied in one of two manners. In the case of dielectric scatterers, the whole object was decomposed into small cylinders, low order harmonic expansions were used to represent the fields from each object, and the recursive algorithm was used to solve the scattering problem. For metallic objects, the equivalence theorem was used to decompose the surface of the scatterer into small

strips, moment methods were then employed to find the individual T-matrices for each strip, and the same T-matrix recursions were used to solve the overall scattering problem. The objective of this letter is to show that one may make use of the cylinder approach (Fig.1) as well for the metallic scattering problem and still obtain highly accurate solutions. In particular, by using cylinders, one may employ the closed-form harmonic expansion method to find the individual scatterers thereby avoiding the moment method computation. In the next section, we will give examples of scattering from circular and rectangular cylinders and the results are verified with those in the literature or analytical calculations.

3 Examples and Discussions

In this section we verify that replacing metallic objects with small metallic cylinders along their perimeters actually produces the results reported in the literature or results obtained analytically. First we define the terms used in this section. The normalized scattering field pattern is defined as:

$$F(\phi) = 10 \log_{10} \left\{ \lim_{r \rightarrow \infty} 2\pi r \frac{|\psi^{sca}(\underline{r})|^2}{\max\{|\psi^{sca}(\underline{r})|^2\}} \right\}. \quad (4)$$

Normalized power density, or the “gain”, is defined as:

$$G_E(\phi) = \lim_{r \rightarrow \infty} \frac{|\psi^{sca}(\underline{r})|^2}{\frac{1}{2\pi} \int_0^{2\pi} |\psi^{sca}(\underline{r})|^2 d\phi}. \quad (5)$$

In all examples the cylinders are embedded in free space with an E_z polarized plane wave incident on them. The first example is the scattering from a single circular cylinder of radius 0.8λ ($ka = 5$). As seen in Fig. 2(a), the cylinder is approximated by 60 smaller cylinders along its circumference which corresponds to a sampling 12 cylinders per wavelength. The normalized scattering field pattern, $F(\phi)$, obtained from the recursive algorithm is plotted against the analytical solution in Fig. 2(b). The second example is the scattering from two circular cylinders with radii of 0.8λ ($ka = 5$) and separated by a distance 2.55λ ($kd = 16$). As in previous example, each cylinder is

approximated by 60 small metallic cylinders with 12 cylinders per wavelength. Fig. 3(a) shows the scattering geometry and Fig. 3(b) compares the normalized scattering patterns obtained using the recursive T-matrix algorithm with those given in [10]. The last example shows the normalized power densities for a slanted rectangular cylinder for two different sizes. The geometry is shown in Fig. 4(a) and the far field power densities, $G_E(\phi)$, for $ka = 3$ and $ka = 5$ ($a = 0.48\lambda$ and $a = 0.8\lambda$, both with $a = 2b$) are depicted in Fig. 4(b). For both cases, the perimeter is sampled at approximately 13 cylinders per wavelength. In this figure, the scattering patterns are compared with the results reported in [11]. As these plots have shown, the scattered fields from metallic objects can be found by replacing these objects with smaller cylinders along the perimeter and then using the recursive T-matrix algorithm of [4].

4 Conclusion

In this letter an alternative discretization along the perimeter of metallic scatterers is used with recursive T-matrix algorithm to calculate the scattered field. The results are verified with previous work.

Abstract—We present the parallel, MPI-based implementation of the SDFMM computer code using a thirty two-node Intel Pentium-based Beowulf cluster. The SDFMM is a fast algorithm that is a hybridization of the Method of Moment (MoM), the Fast Multipole Method (FMM) and the Steepest Descent Integration rule (SDP), which is used to solve large-scale linear systems of equations produced electromagnetic scattering problems. An overall speedup of 7.2 has been achieved on the 32-processor Beowulf cluster and a significant reduced runtime is achieved on the 4-processor 667MHz Alpha workstation.

I. INTRODUCTION

The SDFMM was originally developed at the University of Illinois at Urbana Champaign to analyze large-scale three dimension (3-D) scattering problems [1]–[3]. Recently its computer code has been successfully modified to handle subsurface sensing applications, in particular, the scattering from a PEC and/or penetrable spheroid buried under a two dimensional randomly rough ground surface [4]–[5]. The SDFMM has computational complexity for CPU time and memory equal to only $O(N)$ per iteration versus $O(N^2)$ for the MoM, where N is the total number of the

unknowns [1]. The significantly reduced complexity of the SDFMM over several other computational electromagnetics techniques has enabled efficient Monte Carlo simulation studies [5]. Additional speedup is desirable for increased Monte Carlo sample size or for inverse scattering applications. In this work, we used the MPI library for the parallel implementation of the SDFMM code [6]–[8].

II. PARALLELIZATION

The SDFMM is used to solve the linear system of equations given by [1]–[5]:

$$\bar{\bar{Z}} \bar{I} = \bar{V} \quad (1a)$$

where $\bar{\bar{Z}}$ is the impedance matrix, \bar{I} is the vector of unknown coefficients of the electric and magnetic surface currents and \bar{V} is associated with the incident waves on the rough ground surface.

The matrix $\bar{\bar{Z}}$, which is filled in MoM formulations, becomes sparse with SDFMM and the system of equations in (1a) can be written as:

$$\bar{\bar{Z}}' \bar{I} + \bar{\bar{Z}}'' \bar{I} = \bar{V} \quad (1b)$$

The sparse matrix $\bar{\bar{Z}}'$ has its non-zero elements calculated and stored using the conventional MoM, which are then multiplied by the vector \bar{I} (near field interactions) while the matrix–vector multiply $\bar{\bar{Z}}'' \bar{I}$ is computed in one step without calculating or storing any elements of the matrix $\bar{\bar{Z}}''$. This is achieved by using the FMM hybridized with the SDP integration rule.

The following three bottlenecks in the SDFMM code can benefit from being parallelized: (i) the subroutines that calculates the elements of the sparse matrix $\bar{\bar{Z}}'$; (ii) the subroutines that execute the

matrix vector multiplication $\bar{\bar{Z}}'\bar{I}$ in each iteration of the solver; and (iii) the subroutines that execute the fast multipole method for $\bar{\bar{Z}}''\bar{I}$ (far field interactions).

The computer code has been parallelized by exploiting the underlying available data parallelism. The key data structure in subroutine (i) is the sparse matrix $\bar{\bar{Z}}'$, which is stored as blocks of nonzero elements. These blocks are distributed among all processors, and no additional communication is needed. When this routine is parallelized we achieved near-linear speedups on 32 processors. In the matrix-vector multiplication $\bar{\bar{Z}}'\bar{I}$, the computation is parallelized by distributing \bar{I} to all processors in each iteration. The resulting vector components produced by the multiplication are then distributed to all processors. For bottleneck (iii), there are two involved subroutines to compute the far field interactions consisting of a series of loops with complex interdependences. Each loop is separately parallelized, with collective communication used to distribute the results to all processors after executing each subroutine. In addition these two subroutines are executed in parallel, followed by subsequent distribution of the results to all processors. Load balance between these two subroutines is achieved using a detailed performance model based on the serial execution time of each routine, the time required for collective communication operations, and the amount of communication overhead needed. The structure of the parallelized SDFMM application is shown in Fig. 1.

We evaluated the parallel implementation of the SDFMM computer code on a 32-node Intel Pentium-based Beowulf cluster. Thirty one nodes of the Beowulf cluster are 350MHz Intel Pentium IIs with 256 MB of RAM and one node is a 4x450MHz Intel Pentium II Xeon shared memory processor with 2GB of RAM. The nodes are connected to a 100 BaseTX Ethernet network and they use the SuSE 6.1 operating system with Linux kernel 2.2.13, and the MPICH 1.2.1 implementation of the MPI library. We also tested the parallelized code on a 4-node shared

memory Compaq Alpha-based workstation (667Mhz Alpha 21264) of 16GB total RAM. The processor uses the UNIX OSF/1 V5.1 operating system with the MPICH 1.1.2 MPI library.

Our benchmark includes three small-scale cases executed on the 256MB Intel cluster, and in addition one moderate-scale case that is executed on the Alpha workstation. All results obtained by executing the parallel version of the code are validated with those computed by the serial version of the code [4]–[5]. The scattering problem configurations used in [5] are employed here, but for only one rough surface realization. The rough ground (characterized by Gaussian statistics with zero mean for the height), is described by the rms height (σ) and the correlation length (l_c). In all cases, the relative dielectric constant of the ground soil (dry sand) and the penetrable buried object (TNT in a land mine) are $\epsilon_r = 2.5 - j0.18$ and $\epsilon_r = 2.9 - j0.0092$, respectively, and the ground correlation length is $l_c = 0.5\lambda_0$. A Gaussian beam with horizontal polarization is employed for the incident waves [5]. In Case 2, the buried sphere has radius of $a = 0.16\lambda_0$ with burial depth equal to $z = -0.32\lambda_0$ measured from its center to the mean plane of the ground while in Case 3 and 4 the buried spheroid has dimensions $a = 0.3\lambda_0$ and $b = 0.15\lambda_0$, and is buried at $z = -0.3\lambda_0$. The ground dimensions are $3\lambda_0 \times 3\lambda_0$ in Cases 1–3 and $8\lambda_0 \times 8\lambda_0$ in Case 4. Table I summarizes the parameters and output results for Cases 1–4.

Table I

Case #	# of Unknowns	σ	Object	System	# of Processors	Serial/Par. Time (min.)	Speedup (overall)
1	8,800	$0.3\lambda_0$	None	Cluster	32	99/14	7.1
2	8,800	$0.1\lambda_0$	Sphere	Cluster	32	90/14	6.2
3	8,800	$0.04\lambda_0$	Spheroid	Cluster	32	88/12	7.2

4	60,320	$0.04\lambda_o$	Spheroid	Alpha Server	4	96/37	2.5
---	--------	-----------------	----------	-----------------	---	-------	-----

The speedup of a parallelized application is defined as the ratio of the serial runtime to the parallel runtime. In Fig. 2 the overall speedup and the speedup for the initialization routine (filling matrix $\bar{\bar{Z}}'$) are plotted versus the number of processors for Case 1. The speedup curves for Cases 2 and 3 are similar, with slightly different peak values of 6.2 and 7.2, respectively. The results show the significant speedup in the initialization time that is needed to fill the sparse matrix $\bar{\bar{Z}}'$. This initialization speedup dramatically affects the overall speedup of the code as shown in Fig. 2. In each case the peak overall speedup is observed when running on 32 processors, but most of this speedup is achieved using only 12 processors.

The efficiency of an application for a given number of processors is defined as the ratio of the speedup to the number of processors. Over Cases 1–3, the average speedup on 32 processors is 6.8, giving an efficiency of 0.21. Based on the serial runtimes, 88% of the code is executed in parallel. Therefore by Amdahl's Law [9], the peak speedup achievable for the current parallelization of the code is 8.3. We conclude that communication overhead and load imbalance among the processors accounts for the reduction in speedup from 8.3 to 6.8.

A comparison between the speedups achieved in the other bottlenecks (i)–(iii) mentioned in Section II is also shown in Fig 2. These results demonstrate that the overall speedup is almost the same as that achieved in the matrix–vector multiplication $\bar{\bar{Z}}\bar{\bar{T}}$ which is the bottleneck in (ii).

In the second set of experiments, we solved the moderate–scale problem of Case 4 (60,320 unknowns) on the Alpha SMP using all four available processors. The overall speedup in this case is 2.5 which is close to the predicted peak speedup of 2.9. This implies that executing the parallel

code on the 4-Alpha 667 MHz processor gives an impressive reduced absolute runtime for this moderate-scale case. The serial version of the code requires 950MB of memory, while the parallel version requires 1154MB of memory distributed over four processors (288, 290, 289 and 287MB each). The results of the parallel solution were identical to those of the serial implementation presented in [5].

The results described in this section demonstrate that by exploiting fine-grained parallelism within a single surface realization (one run of the code), we have achieved significant speedups. However, when the number of rough surface realizations is much larger than the number of available processors, as with Monte Carlo simulations, larger speedups are possible. This situation occurs when we need to run Monte Carlo simulations [5]. In this case we assign a group of these realizations (runs of the code) to be executed in parallel on each processor. Since the computations are independent and little communication is needed, this coarse-grained parallelism gives a perfect speedup that is only limited by the number of available processors. In other subsurface scattering configurations, we may need to obtain multiple views of a target buried under the same rough surface realization [4], which requires running the code only few times. A combination of fine and coarse-grained parallelism can make efficient use of all available processors.

III. CONCLUSIONS

MPI is successfully employed for the parallel implementation of the SDFMM. A significant overall speedup of 7.2 has been achieved on the 32-processor Beowulf cluster and a dramatic reduced runtime is gained using the 4-processor Alpha workstation. The greatest potential for speedup occurs in the sparse matrix filling and far field interaction steps.

ACKNOWLEDGEMENTS

The authors would like to thank Prof. W. Chew and Prof. E. Michielssen at UIUC for allowing them the use and modification of the SDFMM computer code for the current application. This research was sponsored by the ERC Program of the NSF under award number EEC-9986821, in

part by the ARO Demining MURI grant # DAA 0-55-97-0013, and in part by the College of Engineering at the University of Arkansas.

I. INTRODUCTION

Through replacement of the real spatial or spatial-temporal source locations in the frequency domain (FD) or time domain (TD) Maxwell field equations by locations in complex space or space-time, respectively, one may generate a new class of exact field solutions which convert point-source-excited fields in any environment into fields excited by Gaussian-beam-like wave objects in that environment (Deschamps, 1971; Felsen, 1976). While most applications of this elegant and physically appealing complex-source-point (CSP) technique have been concerned with "high frequency" tracking of well-collimated "wide-waisted" beams, we shall be concerned here with utilizing a tight superposition of narrow-waisted ray-like CSP beams (centered on a Gabor lattice) for synthesis of FD and TD distributed aperture radiation, and the interaction of these radiated fields with complex propagation and scattering environments. Previous studies have employed this algorithm for FD distributed phased apertures (Maciel and Felsen, 1989) and for transmission of these fields through focal regions and through plane or cylindrically stratified dielectrics (Maciel and Felsen, 1990a,b). Here, we extend this algorithm to FD scattering by a moderately rough perfectly conducting boundary. We also extend the FD aperture radiation algorithm to the short-pulse TD, utilizing CSP pulsed beam wavepackets. The FD problem is considered first.

II. RADIATION AND SCATTERING IN THE FREQUENCY DOMAIN

The problem geometry is shown in Fig. 1a. A y -directed two-dimensional y -independent time-harmonic electric field with suppressed $\exp(-i\omega t)$ dependence and spatial profile $f(x)$ is assumed to occupy the region $|x| \leq d/2$ in the aperture plane $z = z_A$,

$$E_y(x, z_A) = f(x), \quad |x| \leq d/2. \quad (1)$$

This field irradiates a perfectly conducting boundary with sinusoidal height profile

$$h(x) = A[1 - \cos(2\pi x/\Lambda)] \quad (2)$$

Figure 1. Problem geometry and Gabor phase space lattice. (a) Boundary profile: $h_{max} = 2A$; Λ =period. Aperture profile (inset): $f(x) = \cos(\pi x/d)$, $|x| \leq d/2$; $f(x) = 0$, $|x| > d/2$. (b) Gabor lattice: L_x =spatial period; β_x =spectral period.

measured from the $z = 0$ plane. We first consider the aperture problem.

II.a Radiation from aperture distributions

We summarize here essential results from previous publications (Bastiaans, 1980; Einziger and Shapira, 1986; Maciel and Felsen, 1989; Steinberg *et al*, 1991). The field radiated into the half-space $z < z_A$ from the aperture in (1) can be expressed as a line-source superposition (Kirchhoff integration)

$$E_y(x, z) = \frac{\partial}{\partial z} u(x, z), \quad u(x, z) = \frac{i}{2} \int_{-d/2}^{d/2} f(x') H_0^{(1)}(kR) dx', \quad (3)$$

where $k = \omega \sqrt{\epsilon_0 \mu_0} = 2\pi/\lambda$ is the free space wavenumber; λ is the free space wavelength; $H_0^{(1)}(\cdot)$ is the zeroth order Hankel function of the first kind; u is a scalar Debye potential; and

$$R = \sqrt{(x - x')^2 + (z - z_A)^2}. \quad (4)$$

II.b Beam discretization

The aperture field $f(x)$ is to be parameterized in terms of Gaussian beam basis functions via the rigorous self-consistent Gabor series representation

$$f(x) = \sum_{m,n=-\infty}^{\infty} A_{mn} w(x - mL_x) \exp(in\beta_x x), \quad (5)$$

where $w(x)$ represents the normalized Gaussian window

$$w(x) = \left(\frac{\sqrt{2}}{L_x} \right)^{1/2} \exp[-\pi(x/L_x)^2], \quad \int_{-\infty}^{\infty} w^2(x) dx = 1. \quad (6)$$

With k_x representing the x -domain wavenumber, this representation places the beams on a discretized (x, k_x) phase-space lattice (Fig. 1b), on which each lattice point gives rise to a Gaussian beam whose spatial and spectral (tilting) shifts are tagged by the indexes m and n , respectively. Spatial and spectral periods are related by the self-consistency relation (configuration-spectrum tradeoff) $L_x \beta_x = 2\pi$ (Bastiaans, 1980). The expansion coefficients can be computed by introducing an auxiliary function $\gamma(x)$ defined through the *biorthogonality* condition (Bastiaans, 1980),

$$\int_{-\infty}^{\infty} w(x) \gamma^*(x - mL_x) \exp(-in\beta_x x) dx = \delta_m \delta_n, \quad (7)$$

where $*$ denotes the complex conjugate, while $\delta_q = 1$ for $q = 0$ and $\delta_q = 0$ for $q \neq 0$. Accordingly (Bastiaans, 1980),

$$A_{mn} = \int_{-\infty}^{\infty} f(x) \gamma^*(x - mL_x) \exp(-in\beta_x x) dx. \quad (8)$$

For Gaussian windows, the biorthogonal function is given in (Bastiaans, 1980). For numerical computation of the Gabor coefficients, see (Einziger and Shapira, 1986). The radiated potential field in the half-space $z < z_A$ (see (3)) can be represented as (Maciel and Felsen, 1989)

$$u(x, z) = \sum_{m, n=-\infty}^{\infty} A_{mn} B_{mn}(x, z), \quad (9)$$

where the beam functions $B_{mn}(x, z)$ are synthesized by Gabor-weighted line-source superposition

$$B_{mn}(x, z) = \frac{i}{2} \int_{-d/2}^{d/2} w(x' - mL_x) \exp(in\beta_x x') H_0^{(1)}(kR) dx', \quad (10)$$

R being defined in (4). The integral in (10) (or its spectral counterpart) can be evaluated asymptotically in the beam *paraxial far zone*, yielding the following *complex source point* (CSP) approximation (Maciel and Felsen, 1990a)¹,

$$B_{mn}(x, z) \sim 2^{5/4} \left(\frac{L_x}{8\pi k \tilde{R}_{mn}} \right)^{1/2} \exp \left\{ i \left[k \left(\tilde{R}_{mn} + ib \right) + \pi/4 \right] \right\}, \quad (11)$$

with \tilde{R}_{mn} representing the *complex distance* between the observer at $P = (x, z)$ and the *complex source point* (here and henceforth, the tilde \sim denotes a complex quantity),

$$\tilde{P}'_{mn} = (\tilde{x}'_{mn}, \tilde{z}'_{mn}), \quad \tilde{x}'_{mn} = mL_x + ib \sin \theta_n, \quad \tilde{z}'_{mn} = z_A - ib \cos \theta_n, \quad (12)$$

$$\tilde{R}_{mn} = \overline{P \tilde{P}'_{mn}} = \sqrt{(x - \tilde{x}'_{mn})^2 + (z - \tilde{z}'_{mn})^2}. \quad (13)$$

In accord with the radiation condition, the square root is defined by $\text{Re}(\tilde{R}_{mn}) \geq 0$. The displacement parameter (Fresnel length) b is related to the beam lattice period L_x and the beam axis angle $\theta_n = \sin^{-1}(n\lambda/L_x)$ via $b = (L_x \cos \theta_n)^2/\lambda$ (Maciel and Felsen, 1990a), whence (11) is valid in the paraxial far-zone of each beam, $|\tilde{R}_{mn}| \gg b$. For large tilt angles with $n > L_x/\lambda$, the beam tilt angle θ_n is complex and the corresponding beams become *evanescent*.

II.c Narrow-waisted beams

For *narrow-waisted* beams ($L_x \ll d$), the Gabor coefficients can be effectively estimated by *sampling* the aperture field distribution, without performing the integration in (8) (Maciel and Felsen, 1989),

$$A_{mn} \approx \begin{cases} (L_x/\sqrt{2})^{1/2} f(mL_x), & n = 0, \\ 0, & n \neq 0, \end{cases} \quad (14)$$

so that from (9) and (11)

$$u(x, z) \approx \sum_{|m| \leq (d/2L_x)} A_{m0} B_{m0}(x, z), \quad (15)$$

where B_{m0} is obtained from (11) with $n = 0$. The tilted ($n \neq 0$) beams in the Gabor expansion, which generate evanescent "far fields", are ignored in this approximation.

II.d Linearly-phased aperture

Narrow-waisted beams work very well for nonphased apertures, but usually require finer aperture sampling in the presence of phasing (Maciel and Felsen, 1990a). Here we consider a linearly-phased cosine aperture field,

$$f(x) = g(x) \exp(ikx \sin \theta_A), \quad g(x) = \cos(\pi x/d), \quad |x| \leq d/2, \quad (16)$$

where θ_A is the tilt angle of the main radiation lobe with respect to the z axis. In this case, a more effective discretization can be obtained by Gabor-expanding the real function $g(x)$ only, and including the linear phasing in the beam integral (10) for the B_{m0} beam propagator. Accordingly, the narrow-waisted ($L_x \ll d$) beam expansion can be recast as

$$u(x, z) \approx \sum_{|m| \leq (d/2L_x)} C_m B_{m0}(x, z), \quad C_m = (L_x/\sqrt{2})^{1/2} g(mL_x), \quad (17)$$

$$B_{m0}(x, z) \sim 2^{5/4} \left(\frac{L_x}{8\pi k \tilde{R}_{m0}} \right)^{1/2} \exp \left\{ i \left[k \left(\tilde{R}_{m0} + mL_x \sin \theta_A + ib \right) + \pi/4 \right] \right\}, \quad (18)$$

¹ Note that there are some sign changes with respect to (Maciel and Felsen, 1990a), since here we assume propagation into the half-space $z < z_A$.

Figure 2. Linearly phased cosine aperture distribution $f(x) = \cos(\pi x/d) \exp(ikx \sin \theta_A)$ ($d = 10\lambda$, $\theta_A = 30^\circ$). Near-zone radiated potential field $u(x, z)$ at $z_A - z = 5\lambda$ synthesized using narrow-waisted nontilted and tilted beams (with $L_x = 0.02d$) is compared with the Kirchhoff integration reference solution.
— Reference solution; - - - Nontilted beams; ····· Tilted beams.

$$\tilde{R}_{m0} = \sqrt{(x - mL_x - ib \sin \theta_A)^2 + (z - z_A + ib \cos \theta_A)^2}, \quad b = (L_x \cos \theta_A)^2 / \lambda. \quad (19)$$

The beam propagator (18) differs from B_{m0} in (15) by the phase shift $(ikmL_x \sin \theta_A)$ which produces the propagation-matched tilt θ_A in the beam direction. In Fig. 2, the near-zone potential field synthesized using the narrow-waisted tilted beam decomposition in (17) is compared with a calibrated computation-intensive Kirchhoff integration reference solution based on (3), and with the nontilted formulation in (15) when applied to the *entire* aperture field in (16). The tilted beam synthesis is hardly distinguishable from the reference solution, whereas the nontilted synthesis is less accurate in the magnitude.

II.e Reflection from a periodic perfectly conducting boundary

The field radiated by the aperture distribution in (16) is now assumed to impinge on a perfectly conducting moderately rough periodic boundary described by the continuous function $h(x)$ which is assumed to vary slowly over a wavelength scale (Fig. 1a). Moderately rough irregular dielectric interfaces separating two dielectric half-spaces are treated elsewhere (Galdi *et al*, 2000a).

The reflected field can be constructed rigorously by *complex ray tracing* applied to each beam in the aperture decomposition; this requires the analytic continuation, into a complex configuration space, of *all* geometrical parameters involved (with the exception of the observation point). However, *narrow-waisted* beams can be tracked accurately and much more efficiently via a beam-tracing paraxial *almost real ray-tracing* scheme (Ruan and Felsen, 1986; Maciel and Felsen, 1990b)), valid in appropriately calibrated observation ranges. For the new application to a periodic boundary, we first treat the canonical problem of CSP Gaussian beam reflection from a curved segment on a conducting boundary. The problem geometry is illustrated in Fig. 3.

An incident Gaussian beam is generated by a CSP at

$$\tilde{P}_s = (\tilde{x}_s, \tilde{z}_s), \quad \tilde{x}_s = x_s + ib \cos \alpha_s, \quad \tilde{z}_s = z_s + ib \sin \alpha_s, \quad (20)$$

α_s being the beam axis *real* departure angle with respect to the x axis. For electrically large and smooth scatterers, and when the observation point $P = (x, z)$ lies in the paraxial region of a reflected beam ($\Delta \ll (|\tilde{F}_{r0} P_0|^2 + b^2)^{1/2}$ in Fig. 3), the field can be approximated in terms of the on-axis field of that beam (at P_0) and a complex phase correction. Denoting the on-axis parameters by the subscript zero, one finds for the potential field (Ruan and Felsen, 1986)

$$u^{refl}(P) \approx u^{refl}(P_0) \big|_{\tilde{P}_i=P_{i0}} \exp(ik\tilde{\delta}_p) = \Gamma u^{inc}(P_{i0}) \left(\frac{\tilde{f}_{r0}}{\tilde{R}_0} \right)^{1/2} \exp \left[ik(L_{r0} + \tilde{\delta}_p) \right], \quad (21)$$

$$\tilde{f}_{r0} = \frac{\tilde{L}_{i0} r_c \cos \theta_i}{2\tilde{L}_{i0} + r_c \cos \theta_i}, \quad r_c = - \frac{[1 + (h'(x_{i0}))^2]^{3/2}}{h''(x_{i0})}, \quad ' \equiv d/dx. \quad (22)$$

Figure 3. CSP beam reflection at a curved conducting boundary described by the contour $h(x)$.

Here (see Fig. 3): $\tilde{R}_0 = \overline{\tilde{F}_{r0}P_0}$; $\tilde{R} = \overline{\tilde{F}_{r0}P}$; $\tilde{L}_{i0} = \overline{\tilde{P}_sP_{i0}}$; $L_{r0} = \overline{P_{i0}P_0}$; $\delta_p = \tilde{R} - \tilde{R}_0$ is the complex phase correction; $\tilde{F}_{r0} = (x_{i0} - \tilde{f}_{r0} \cos \alpha_r, z_{i0} - \tilde{f}_{r0} \sin \alpha_r)$ is the *complex* (virtual) focus obtained by analytic continuation of the standard ray-optical formulas (Felsen and Marcuvitz, 1973, p. 168); the *complex* incidence point \tilde{P}_i is approximated by the *real* beam-axis incidence point $P_{i0} = (x_{i0}, z_{i0})$; α_r is the reflected-beam-axis real departure angle with respect to the x axis; r_c is the curvature radius at P_{i0} ; and $\Gamma = 1$ is the plane-wave potential field reflection coefficient. As shown in (Ruan and Felsen, 1986), this scheme corresponds to tracing a ray along a *complex* trajectory from the CSP at \tilde{P}_s to the intersection P_{i0} of the *real* beam axis with the *real* surface; from there, the path to the observer proceeds entirely in *real* configuration space, along the beam axis. Multiple reflections, which may occur in the configuration in Fig. 1a, can be incorporated by iterating (21), whereby the complex focus (either virtual or real) associated with each iteration becomes the phase reference for the next iteration (Galdi *et al.*, 2000a). Apart from the complex ray connecting the CSP to the first real incidence point, the multi-hop path to the observer proceeds entirely in *real* configuration space along the beam axes, and the phase correction is applied only on the last path segment leading to the observer.

II.f Application: infinite sinusoidal boundary

For a first check on the applicability of the narrow-beam algorithm to surface scattering problems, we have considered the sinusoidal boundary in Fig. 1a illuminated by a nonphased cosine aperture distribution with wavelength λ . Extensive numerical experiments have been performed for various observation heights z and aperture heights z_A ; profiles $h(x)$ with various minimum curvature radii r_c ; and various beam lattice spacings L_x . All of these numerical implementations for the scattered potential field have been compared with a numerically integrated, computation intensive Physical Optics-Kirchhoff reference solution based on (3); by previous calibration, Physical Optics has been confirmed to apply to the profile parameters under consideration here. Typical results for the potential u^{refl} are displayed in Fig. 4. In general, we have found that the accuracy of the narrow-waisted beam algorithm *improves* for *greater observation distance* (because of the far-zone paraxial approximation), but even at moderate distances the agreement is satisfactory. We also found that the beam algorithm is quite robust with respect to *scramblings* of the Gabor lattice. As discussed in (Maciel and Felsen, 1990b), this feature can be exploited to obtain *a priori* accuracy assessments when reference solutions are not available. For the present nonphased aperture example, we found the best tradeoff between accuracy and computational cost to occur for $L_x \sim \lambda$. A *finer* sampling may, however, be required for *phased* aperture field distributions. On the other hand, the accuracy gets *worse* as the *distance of the aperture from the surface increases*. We found that in order to get robust and accurate predictions, we should have $z_A - h_{max} \leq \lambda$, where h_{max} is the maximum of the boundary profile. However, this is not a very restrictive limitation since it is always possible (and computationally cheap because of the simple determination of the Gabor coefficients via (14)) to perform a multi-step Gabor decomposition for greater aperture-to-boundary distances, i.e., project the beam-computed radiated potential field onto a virtual aperture suitably close to the surface and then again apply the narrow-waisted beam algorithm. Concerning degradation of accuracy with *increase* in wavelength, we found that even for relatively "low-frequency" geometries, i.e. moderate (minimum r_c)/ λ as in Fig. 4b, the beam algorithm, though no longer *highly* accurate, still provides reasonably good predictions (for details, see (Galdi *et al.*, 2000a)).

Figure 4. Beam-computed reflected potential $u(x, z)$ and Physical Optics (PO) reference solution. (a) Aperture: width $d = 100\lambda$; height $z_A = 11\lambda$. Boundary: period $\Lambda = 50\lambda$; height $h_{max} = 2A = 10\lambda$; minimum $r_c = 12\lambda$; maximum slope $\phi_{max} = 32^\circ$. Beam lattice period: $L_x = 0.01d = \lambda$. Observation plane at $z_{obs} = 50\lambda$. (b) $d = 20\lambda$; $z_A = 3\lambda$; $\Lambda = 10\lambda$; $h_{max} = 2A = 2\lambda$; minimum $r_c = 2.5\lambda$; $\phi_{max} = 32^\circ$; $L_x = 0.05d = \lambda$; $z_{obs} = 10\lambda$. Because the reflected field is symmetric with respect to $x = 0$, only the $x > 0$ portion is shown over the range $0 \leq x \leq 2\Lambda$. — PO reference solution; - - - Beams.

III. TIME DOMAIN RADIATION FROM DISTRIBUTED APERTURES

We shall now explore the extension of the FD results for aperture radiation in Sec. II.a to time-dependent excitation, in particular to short pulses. To this end, we consider a space-time aperture field distribution at $z = 0$ with separable space-time dependence and linear time delay

$$e_y(x, 0, t) = f(x, t), \quad |x| \leq d/2, \quad f(x, t) = g(x)p(t - c^{-1}x \sin \theta_A), \quad (23)$$

where c is the speed of light and $p(t)$ is a pulse with characteristic width T_p . This distribution represents the TD counterpart of the linearly-phased time-harmonic aperture in (16). The present TD formulation is restricted to the radiated field only, and we analyze the propagation into the $z > 0$ halfspace, wherein (23) gives rise to a space-time pulse propagating in the θ_A direction (Fig. 5). It is assumed that the normalized width of the pulse is much shorter than the aperture dimension d , i.e., $cT_p \ll d$.

III.a Reference solution

Using the two-dimensional TD Green's function

$$G(x, z, t; x', z', t') = \frac{1}{2\pi\sqrt{(t-t')^2 - (s/c)^2}} H[(t-t') - s/c], \quad s(z') = \sqrt{(x-x')^2 + (z-z')^2}, \quad (24)$$

where $H(\cdot)$ is the Heaviside step function, the field radiated into the half-space $z > 0$ can be represented as a space-time Kirchhoff integration (Morse and Feshbach, 1973, Sec. 7.3; Kragalott *et al.*, 1997),

$$e_y(x, z, t) = \frac{z}{\pi} \int_{-d/2}^{d/2} dx' \frac{1}{s(0)^2} \int_{-\infty}^{t-s(0)/c} \frac{(t-t') \frac{\partial f}{\partial t'}(x', t')}{\sqrt{(t-t')^2 - (s(0)/c)^2}} dt'. \quad (25)$$

Direct numerical integration of (25) is complicated by the square-root (integrable) singularity at the upper limit $t' = t - s(0)/c$, and requires special care. We have used the Newton-Cotes scheme (Kragalott *et al.*, 1997) for the numerical integration of (25), which represents our reference solution.

III.b Beam discretization

The formal extension of the Gabor-based time-harmonic aperture radiation to time-dependent excitation involves a four-index Gabor series set on a discretized lattice in an eight-dimensional phase space (space-wavenumber, time-frequency). For a rigorous treatment and computational issues, see (Steinberg and Heyman, 1991). We shall explore to what extent the narrow-waisted beam approach,

Figure 5. Linear-delay space-time aperture field distribution and pulsed beam coordinates.

effective for time-harmonic excitation, can be generalized to TD (short-pulse) excitation. The linear-delay aperture field distribution (23) admits the equivalent spectral representation

$$\hat{f}(x, \omega) \equiv \int_{-\infty}^{\infty} f(x, t) \exp(i\omega t) dt = g(x) P(\omega) \exp(ikx \sin \theta_A), \quad P(\omega) = \int_{-\infty}^{\infty} p(t) \exp(i\omega t) dt. \quad (26)$$

A TD beam discretization can be obtained by Fourier-inverting the narrow-waisted tilted beam expansion (17) for the FD linearly-phased aperture presented in Sec. II.d. In order to accommodate the evanescent spectra in the FD beam propagators (18), we use the *analytic signal* formulation instead of the standard Fourier transform (Heyman and Melamed, 1998). Concerning the beam lattice discretization, one can choose a frequency-independent beam lattice period L_x (resulting in a frequency-dependent beam parameter b), or a frequency-independent beam parameter b (resulting in a frequency-dependent L_x). We choose L_x frequency-independent because it yields frequency-independent Gabor coefficients (see (17)). The TD counterpart of the narrow-waisted FD beam expansion (17) for the aperture field distribution (26), with reference to the y -directed electric field, can be thus written as

$$e_y(x, z, t) \approx \sum_{|m| \leq (d/2L_x)} c_m \mathbf{b}_m(x, z, t), \quad c_m = (L_x/\sqrt{2})^{1/2} g(mL_x). \quad (27)$$

The pulsed beam propagator \mathbf{b}_m is the TD counterpart of the FD paraxial, far-zone beam propagator in (18), with (19)² (for simplicity, the subscript " m_0 " is henceforth replaced by " m ")

$$\mathcal{B}_m(x, z, \omega) = -ik2^{5/4} \left(\frac{L_x}{8\pi k} \right)^{1/2} \exp \left\{ i \left[k \left(\tilde{R}_m + mL_x \sin \theta_A + ib \right) + \pi/4 \right] \right\} \frac{(z - ib \cos \theta_A)}{\tilde{R}_m^{3/2}}, \quad (28)$$

$$\tilde{R}_m = \sqrt{(x - mL_x - ib \sin \theta_A)^2 + (z - ib \cos \theta_A)^2}, \quad b = (L_x \cos \theta_A)^2 / \lambda. \quad (29)$$

Via the analytic signal formulation, one has (Re=real part)

$$\mathbf{b}_m(x, z, t) = \text{Re} \left[\frac{1}{\pi} \int_0^\infty \mathcal{B}_m(x, z, \omega) P(\omega) \exp(-i\omega t) d\omega \right]. \quad (30)$$

While the integral in (30) cannot be evaluated explicitly in general, we have found useful closed-form approximations for the important class of Gaussian pulses. In particular, we consider a Rayleigh (four-times-differentiated Gaussian) pulse

$$p(t) = \exp \left[-\frac{50(t - T_p/2)^2}{T_p^2} \right] \left[1 + \frac{10000(t - T_p/2)^4 - 600(t - T_p/2)^2 T_p^2}{3T_p^4} \right], \quad (31)$$

²Note that (28), (29) are slightly different from (18), (19), since here the electric field is considered instead of the potential, the aperture plane is located at $z_A = 0$, and propagation is into the $z > 0$ halfspace.

but the procedure presented below can be applied to any kind of modulated or differentiated Gaussian.

Since the beam lattice period L_x has been chosen frequency independent, the beam parameter b and hence the complex distance \tilde{R}_m in (29) are *frequency dependent*. For $z \gg |b \cos \theta_A|$, we can approximate in the amplitude factor of (28)

$$\frac{(z - ib \cos \theta_A)}{\tilde{R}_m^{3/2}} \approx \frac{z}{R_m^{3/2}}, \quad R_m = \sqrt{(x - mL_x)^2 + z^2}, \quad (32)$$

rendering the distance R_m *real*. In the phase, we retain the first order paraxial correction

$$\tilde{R}_m \approx z_{bm} - ib + \frac{x_{bm}^2(z_{bm} + ib)}{2z_{bm}^2}, \quad (33)$$

valid for $|z_{bm} - ib| \gg |x_{bm}|$ and $z_{bm} \gg b$; here x_{bm}, z_{bm} are the beam coordinates (see Fig. 5)

$$\begin{bmatrix} x_{bm} \\ z_{bm} \end{bmatrix} = \begin{bmatrix} \cos \theta_A & -\sin \theta_A \\ \sin \theta_A & \cos \theta_A \end{bmatrix} \begin{bmatrix} x - mL_x \\ z \end{bmatrix}. \quad (34)$$

In the TD, the beam parameter b must be small over the entire bandwidth Ω_p of $p(t)$ in (31),

$$b = \frac{(L_x \cos \theta_A)^2 \omega}{2\pi c} \ll z_{bm}, \quad \omega \leq \Omega_p. \quad (35)$$

With these assumptions, the integral in (30) can be reduced to the generic form (the spectrum $P(\omega)$ of $p(t)$ in (31) is evaluated readily),

$$\int_0^\infty \omega^{9/2} \exp(\xi\omega + \zeta\omega^2) d\omega, \quad \text{Re}(\zeta) < 0, \quad (36)$$

which can be expressed in terms of confluent hypergeometric functions (Abramowitz and Stegun, 1964, Sec. 13). Accordingly, the TD beam propagator can be written explicitly as

$$b_m(x, z, t) = \text{Re} \left\{ \eta \left[13\alpha \Gamma\left(\frac{11}{4}\right) G_1\left(5\sqrt{\frac{\pi}{2}}\frac{\beta}{\alpha}\right) + 20i\sqrt{2\pi}\beta \Gamma\left(\frac{17}{4}\right) G_2\left(5\sqrt{\frac{\pi}{2}}\frac{\beta}{\alpha}\right) \right] \right\}, \quad (37)$$

$$\alpha = \sqrt{\pi(cT_p z_{bm})^2 + 50(L_x x_{bm} \cos \theta_A)^2}, \quad \beta = x_{bm}^2 + z_{bm}(2z_{bm} + cT_p - 2ct) + 2L_x m z_{bm} \sin \theta_A, \quad (38)$$

$$\eta = \frac{4z\sqrt{10L_x}\pi^{7/4}T_p^5(cz_{bm})^{11/2}\exp(-i\pi/4)}{39\sqrt{c}R_m^{3/2}\alpha^{13/2}}, \quad G_1(v) = M\left(\frac{11}{4}, \frac{1}{2}, -v^2\right), \quad G_2(v) = M\left(\frac{13}{4}, \frac{3}{2}, -v^2\right), \quad (39)$$

where R_m, x_{bm} and z_{bm} are defined in (32) and (34); $\Gamma(\cdot)$ is the gamma function (Abramowitz and Stegun, 1964, Sec. 6); and $M(q, s, v)$ is the confluent hypergeometric function (Abramowitz and Stegun, 1964, Sec. 13). The above procedure can be applied to *any* Gaussian pulse; modulation or differentiation only affects the q, s arguments of M . We found simple rapidly converging approximations for the functions G_1 and G_2 in the form $G_{1,2} \sim \exp(-v^2)$ (power series in v^2) (Galdi *et al*, 2000b). These functions resemble the functional form of the time pulse excitation in (31). Using these approximations the TD beam propagator in (37) can be computed efficiently.

III.c Assessment of accuracy

The restriction in (35) is the most serious because, for specified Ω_p, θ_A , and observation point, it determines the maximum allowable lattice period (i.e., the minimum number of beams). The overall constraint can be expressed as (Galdi *et al*, 2000b)

$$Q \equiv \frac{L_x}{d} \sqrt{\frac{\kappa \cos^3 \theta_A}{\chi}} \ll 1, \quad (40)$$

where $\chi = z_{obs}/F$ is the distance of the observation plane scaled by the Fresnel distance of the aperture, $F = d^2/(cT_p)$; $\kappa = \Omega_p T_p/2\pi$ is the normalized bandwidth of the pulse $p(t)$; and L_x/d determines the number of beams in the expansion (27). The nondimensional estimator $Q \ll 1$ expresses the range of validity of the algorithm in terms of all relevant parameters of the problem. For example, increasing the lattice period L_x (i.e., decreasing the number of beams) can be compensated by a corresponding

Figure 6. Nonphased ($\theta_A = 0$) sine aperture distribution with $cT_p = 0.5$, $d = 5 = 10cT_p$ (arbitrary units). TD narrow-waisted beam synthesis (for various values of the beam-lattice period) is compared with space-time Kirchhoff integration (reference solution). (a) Time evolution at a fixed observation point $x = 1.25$, $z = 5 = 0.1F$ (arbitrary units); (b) transverse cut (spatial profile) at $z = 5$, $ct = 5.25$.
— Reference solution; - - - Beams ($L_x = d/20$, $Q = 0.45$); $\cdots\cdots$ Beams ($L_x = d/50$, $Q = 0.18$); - - - - Beams ($L_x = d/100$, $Q = 0.09$).

Figure 7. Parameters as in Fig. 6, but with linear delay ($\theta_A = 30^\circ$). (a) Time evolution at a fixed observation point $x = 4.14$, $z = 5 = 0.1F$; (b) transverse cut at $z = 5$, $ct = 6.7$.
— Reference solution; - - - Beams ($L_x = d/20$, $Q = 0.36$); $\cdots\cdots$ Beams ($L_x = d/50$, $Q = 0.14$); - - - - Beams ($L_x = d/100$, $Q = 0.07$).

increase of $(z_{obs})^{1/2}$. In order to assess the accuracy of the proposed TD beam expansion, we have performed computations for the linear-delay space-time aperture distribution (23) with a sine spatial tapering, $g(x) = \sin(2\pi x/d)$, $|x| \leq d/2$, excited by the Rayleigh time pulse (31). Figure 6a shows the time evolution of the y -directed electric field at a fixed observation point (x, z) in the near zone ($z = 0.1F$) of a large aperture ($d = 10cT_p$) without phase delay ($\theta_A = 0$), computed via the space-time Kirchhoff integration (25), and via the TD beam synthesis (27) with various beam lattice periods. As expected, the agreement improves as the beam lattice period L_x decreases, and satisfactory accuracy is achieved for $Q \leq 0.1$ (for this example $\kappa \sim 8$). It is observed from the transverse cut in Fig. 6b that, despite the use of the paraxial paraxial far-zone approximation, the TD beam synthesis is quite accurate even in the near zone of the aperture ($z = 0.1F$) and not only around the main radiation lobes. We found that, as the observation distance increases, a coarser discretization can be used according to (40); even at moderate distances, quite accurate syntheses can be achieved with a relatively small number of beams (~ 50) (Galdi *et al.*, 2000b). The corresponding results for linear-delay ($\theta_A = 30^\circ$) are shown in Fig. 7 and the same considerations apply.

IV. CONCLUSIONS

In many current forward and inverse scattering scenarios, there is a need for numerically efficient robust

forward solvers for fields excited by distributed sources in the presence of complex environments. This motivation has led us to re-visit the previously developed FD narrow-waisted Gaussian beam algorithms (Maciel and Felsen, 1989; 1990a,b) and to extend them to new FD applications as well as to the short-pulse TD. The outcomes from the rough sinusoidal scattering example here, as well as the first results in the TD, are encouraging. Further FD extensions to irregularly rough interfaces between dielectrics are already in progress, as are TD interactions with canonical scatterers to learn the new rules.

ACKNOWLEDGEMENTS

The authors acknowledge fruitful discussions with Professor D.A. Castañon (Boston University) on forward and inverse scattering and imaging which motivated this investigation. We also acknowledge partial support by ODDR&E under MURI grants ARO DAAG55-97-1-0013 and AFOSR F49620-96-1-0028. In addition, VG acknowledges a European Union postdoctoral fellowship through the University of Sannio, Benevento, Italy.

Abstract

In this paper, we present a new technique for determining the surface profile of a moderately rough interface between air and a homogeneous dielectric half-space. Based on sparsely sampled step-frequency ground penetrating radar measurements, the proposed inversion scheme uses a quasi-ray Gaussian beam fast forward model, coupled with a low-order parameterization of the surface profile in terms of B-splines. The profile estimation problem is posed as a parameter optimization problem, which is solved using a multiresolution continuation method via *frequency hopping*. Numerical experiments establish that the algorithm is efficient, and yields accurate reconstructions throughout most of the illuminated region even in noisy environments, losing accuracy only in regions with very weak illumination.

Keywords

Ground penetrating radars, rough surfaces, inverse scattering, Gaussian beams.

I. INTRODUCTION

The problem of determining the properties of rough surfaces from electromagnetic (EM) reflected field data arises in many important applications, ranging from nondestructive testing to underground imaging. In this paper, we address underground imaging via ground-penetrating radar (GPR). In GPR systems, arrays of above-ground transmitters and receivers illuminate areas of interest, and receive backscattered signals from underground objects and from surface reflections. The shape of the air-ground interface is unknown, and constitutes a principal corruptor of the backscattered signal from subsurface targets of interest. In order to enhance subsequent detection, classification and inverse scattering processing, it is important to compensate for the distortion introduced by the air-ground interface.

One possible approach for this compensation is to characterize the statistics of the distortion caused by unknown rough surfaces, and then apply appropriate statistical signal processing techniques. Such an approach was used in [1]–[4] for detection of buried mines via both forward-looking and downward-looking GPR systems. However, this approach fails to exploit deterministic information present in the received signals due to scattering from the air-ground interface, and thus yields limited accuracy and robustness in classification and reconstruction (see, e.g., [5]). In this paper, we address the problem of estimating the profile of the air-ground interface from in-situ frequency-stepped GPR measurements, for use in subsequent imaging and classification processing.

Estimation of rough surfaces from inverse scattering has received considerable attention in the past decade. However, most of the available algorithms have focused on conducting surfaces. Wombell and DeSanto [6], [7] used Kirchhoff approximation and Fourier transform to estimate surface profiles based on measurements of the reflected field in all spectral directions. Noguchi and his colleagues [8], [9] used nonlinear optimization techniques for direct estimation of surfaces illuminated by monochromatic Gaussian beams, based on the far-field scattering amplitude for all spectral directions. In a different approach, Schatzberg and Devaney [10] used Rytov approximation and backpropagation to estimate surface profiles based on full measurements of the reflected wave.

In contrast with the above contributions, our work in this paper is focused on estimating surface profiles based on reflection from a moderately rough interface between air and a homogeneous dielectric half-space (soil), as illustrated in Fig. 1. Furthermore, we assume that the reflected field is measured only at receivers with discrete spatial locations, using a stepped-frequency GPR. We assume that the incident field arises from a discrete set of transmitters, and thus has a finite aperture.

First we employ a forward model relating the measured fields at the receivers to the surface profile. This model, detailed in [11], utilizes Gabor-based Gaussian beam algorithms in conjunction with the complex source point (CSP) method for generating beam-like wave objects [12]–[14]. With this model, together with a parametric representation of the surface in terms of B-splines [15], the surface estimation problem is posed as a nonlinear optimization problem, similar in spirit to the approach in [8]. We show that this optimization problem has local minima, and exploit a multiresolution continuation strategy based on *frequency hopping* [16]–[18], to approach convergence to globally optimal estimates of surface profiles.

The rest of this paper is organized as follows: Section II describes the problem of rough surface reconstruction from frequency-stepped GPR measurements, and poses the estimation problem as a nonlinear optimization problem. Section III describes the surface parameterization, the Gabor-based Gaussian beam algorithm, the multiresolution continuation algorithm, and the resulting optimization approach for determining the surface profile. Section IV details the results of numerical experiments to illustrate the accuracy

of the surface reconstructions under different conditions. Section V provides concluding remarks.

II. STATEMENT OF THE PROBLEM

The problem of interest is reconstructing the air-ground interface coarse-scale profile from a limited number of spatially sampled reflected field measurements, using a limited aperture illumination from a frequency-stepped GPR system. We consider a two-dimensional (2D) model, as depicted in Fig. 1, where a TM-polarized EM field with implicit time-harmonic dependence $\exp(-i\omega t)$ illuminates a dielectric half-space with known relative permittivity ϵ_r and a moderately rough interface, whose coarse scale profile is described by a continuous function $h(x)$. The field is assumed to be generated by an extended aperture distribution at $z = z_A$,

$$\mathbf{E}^{inc}(x, z_A) = f(x)\mathbf{u}_y, \quad |x| \leq d/2, \quad z = z_A, \quad (1)$$

where \mathbf{u}_y denotes a y -directed unit vector.

In this preliminary investigation, we neglect the presence of any buried object; surface estimation strategies in the presence of shallowly buried plastic mine-like targets, not very different in principle, are dealt with elsewhere [19]–[22]. Furthermore, we also neglect the *noisy* (incoherent) contribution of finer-scale roughness, and focus on estimation of the coarse shape, acknowledging the implicit limits of retrievable information through inverse scattering (see, e.g., [23], and the more relevant *near-proximity* extension [24]). The y -directed reflected electric field is sampled at a number N_r of fixed receiver locations $x_1^r, \dots, x_{N_r}^r$ at the observation plane $z = z^r$. As common in many GPR systems, we assume to work in a *step-frequency* regime with N_λ different operating wavelengths (frequencies), so that a set of $N_r \times N_\lambda$ complex (magnitude and phase) samples constitutes the *observed data* of the problem. It is well-known that this inverse scattering problem is *ill-posed*, and therefore a *blind* implementation of inverse scattering techniques would result in *ill-conditioned* numerical algorithms. We refer the interested reader to [23], [24] for analysis of the *retrievable information* from both theoretical and computational viewpoints.

Here, a *robust* inversion strategy via a well-posed inverse of the problem is achieved by

- i) Introducing a finite-dimensional compact geometrical parameterization of the unknown interface profile;
- ii) Estimating the unknown parameters by *fitting* the model-based forward scattering prediction to the available (measured/simulated) data, i.e., minimizing a suitable *cost functional*.

A key issue in this robust strategy is selection of an appropriate interface profile parameterization. This requires tradeoff between versatility, compactness and computational burden, bearing in mind that the number of unknown parameters to be estimated must be *smaller* than the collected reflected data size. Therefore, assuming that the collected data are *non-redundant* [23], [24], the maximum number of parameters that can be reliably estimated is $\sim N_r \times N_\lambda$. For the purposes of this paper, we assume that the surface shape can be approximated by a finite set of basis functions with unknown coefficients,

$$h(x) \approx \sum_{n=1}^N c_n s_n(x). \quad (2)$$

Let $\mathcal{E}_y^{refl}(x_p^r, \lambda_q)$ denote the complex reflected field *measured* at wavelength λ_q at receiver location x_p^r . Let \underline{c} denote the vector of coefficients $c_n, n = 1, \dots, N$. Given a vector of coefficients \underline{c} and the outgoing field from the aperture distribution in (1), we can use the Gabor-based Gaussian beam algorithm in [11] (see also Sec. III-B) for the surface profile in (2) to generate predictions of the reflected field at each receiver. Let $E_y^{refl}(x_p^r, \lambda_q; \underline{c})$ denote the complex reflected field *predicted* from \underline{c} at (free-space) wavelength λ_q at receiver location x_p^r . With this notation, we define the weighted approximation error $J(\underline{c})$ as follows:

$$J(\underline{c}) = \|\underline{E}^{refl}(\underline{c}) - \underline{\mathcal{E}}^{refl}\|^2 = \sum_{p=1}^{N_r} \sum_{q=1}^{N_\lambda} \alpha_{pq} \left| E_y^{refl}(x_p^r, \lambda_q; \underline{c}) - \mathcal{E}_y^{refl}(x_p^r, \lambda_q) \right|^2, \quad (3)$$

for receiver locations $x_1^r, \dots, x_{N_r}^r$ and operating wavelengths $\lambda_1, \dots, \lambda_{N_\lambda}$, $\alpha_{pq} > 0$ being (arbitrary) weight coefficients.

The regularized inverse scattering problem can now be formalized as finding the coefficient vector \underline{c} in (2) which minimizes the cost functional (3), i.e., finding $\hat{\underline{c}}$ such that

$$\hat{\underline{c}} = \arg \min_{\underline{c}} J(\underline{c}) \quad (4)$$

In general, the predictive model $E_y^{refl}(x_p^r, \lambda_q; \underline{c})$ is a highly nonlinear function of the coefficients \underline{c} . Thus, the resulting minimization problem may have multiple local minima. In the next section, we describe the choice of basis functions used in our representation, the forward scattering model, and the optimization approach used for determining global minima of the cost functional (3).

III. ALGORITHMIC ASPECTS

A. Interface Profile Parameterization

As our choice of basis functions in (2), we used shifted B-splines [15] selected with a fixed resolution matched to the coarse level of detail for the reconstruction. In particular, we chose a quartic-spline basis function $s^{(4)}(x)$, where

$$s^{(4)}(X) = \begin{cases} \frac{8}{115}X^4, & 0 \leq X < 1, \\ -\frac{8}{115}(5 - 20X + 30X^2 - 20X^3 + 4X^4), & 1 \leq X < 2, \\ \frac{8}{115}(155 - 300X + 210X^2 - 60X^3 + 6X^4), & 2 \leq X < 3, \\ -\frac{8}{115}(655 - 780X + 330X^2 - 60X^3 + 4X^4), & 3 \leq X < 4, \\ \frac{8}{115}(X - 5)^4, & 4 \leq X < 5, \end{cases} \quad (5)$$

and $X = x/\Delta_x$. This basis function has finite support and differentiable second derivatives (see Fig. 2). The surface profile is thus approximated as a linear combination of shifted B-spline basis functions,

$$h(x) \approx \sum_{n=-4}^{N_h-1} c_n s^{(4)}(x - x_n), \quad x_{min} \leq x \leq x_{max}, \quad (6)$$

$$x_n = x_{min} + n\Delta_x, \quad \Delta_x = (x_{max} - x_{min})/N_h. \quad (7)$$

The resulting linear combination (6) is a triply differentiable function with $N_h + 4$ degrees of freedom. We tried using cubic splines, but did not obtain satisfactory accuracy for the

forward (beam) solver. We can speculate that the differentiability of the *second* derivative (and hence of the radius of curvature) is required by the beam algorithm. In this investigation, we assume *a priori* knowledge of the scale parameter Δ_x in (6) (i.e., the number of B-spline basis functions), and focus on retrieving the unknown coefficients c_n only. A more general *adaptive* framework is presented in [25].

B. The Gabor-Based Gaussian Beam Algorithm

The forward scattering predictive model is detailed in [11]. It is based on a recently developed Gabor-based narrow-waisted Gaussian beam (NW-GB) algorithm for reflection from, and transmission through, moderately rough dielectric interfaces. The main steps of the algorithm can be summarized as follows:

1. The aperture field distribution in (1) is discretized self-consistently via Gabor expansion in terms of *narrow* Gaussian basis functions, which generate narrow-waisted *ray-like* Gaussian beams (GBs) launched from points on the aperture.
2. Each individual GB interaction with the rough interface is tracked via the complex-source-point (CSP) paraxial scheme (*quasi-real* ray tracing) developed in [14] for circular cylindrical dielectric layers, and generalized in [11] to rough surface geometries.
3. The various reflected/transmitted GB contributions are recombined at the observer.

In [11], the NW-GB algorithm has been validated and calibrated against an independently generated rigorous numerical solution [26], and has been shown to provide accurate and robust predictions over a range of calibrated combinations of the problem parameters, including moderate roughness with maximum slopes $\lesssim 40^\circ$, (average) curvature radii R_c larger than a wavelength, incidence directions far from grazing (incidence angles $\lesssim 30^\circ$ relative to z), and dielectric contrasts with $\text{Re}(\epsilon_r)$ ranging from 1.2 to 10 and $\text{Im}(\epsilon_r)$ up to 0.5. Though based on high-frequency asymptotics, the algorithm was found to provide satisfactory accuracy even for relatively *low-frequency* geometries ($R_c \sim 0.5\lambda$) and near-zone observation distances ($z^r \sim \lambda$). We refer the interested reader to [11] for theoretical and computational details, and to [27] for extension to pulsed excitation.

As noted earlier, the computational feasibility of the proposed nonlinear inverse scattering algorithm is strongly tied to the efficiency of the forward solver. In this connection, full-wave techniques are most likely not affordable in terms of computing time and

resources. Conversely, NW-GB algorithms, though not suffering from failures near caustics and other ray-field transition regions, preserve the attractive computational features of standard ray methods in the presence of large computational domains, with minimal memory requirements and typical computing times (for a field sample at a single position) of about 5 – 10ms on a 500 MHz PC, which are fairly shorter than those typical of full-wave techniques. Application of GB algorithms to inverse scattering scenarios was also suggested in [28], where they were found to provide a good tradeoff between accuracy and computational burden.

C. Optimization Strategy

As discussed in Section II, we want a vector of coefficients \underline{c} to minimize the weighted error functional (3). As stated previously, this minimization is nontrivial since the cost functional in (3) is likely non-convex with respect to \underline{c} ; therefore, unless an accurate initial guess is available, standard descent-based optimization algorithms [29] are likely to end in local minima, which correspond to *spurious* solutions. To illustrate this issue, we considered a simplified experiment where all unknown coefficients were set to their true value, with the exception of two that are left variable. The resulting cost function has two degrees of freedom, and can be easily displayed. The interface profile and experiment parameters are shown in Fig. 3. A nonphased cosine tapered aperture illumination

$$f(x) = \begin{cases} \cos(\pi x/d), & |x| \leq d/2, \\ 0, & |x| > d/2, \end{cases} \quad (8)$$

was assumed, with the aperture width d chosen so as to irradiate the region of interest while avoiding edge effects.

In this example, the surface profile was generated randomly by using 16 B-spline basis functions ($N_h = 12$). We chose c_2 and c_6 as unknown and set the remaining 14 coefficients to their true value. Figure 4 shows the resulting 2D cost function, as a function of c_2 and c_6 scaled with respect to their true values $c_2^{(true)}$, $c_6^{(true)}$, respectively. As the figure illustrates, the cost function has a deep *global* minimum at $(c_2, c_6) \approx (c_2^{(true)}, c_6^{(true)})$, but also has a number of *local* minima. This behavior was verified for multiple choices of weight coefficients α_{pq} , thus confirming that standard descent optimization techniques

(e.g., conjugate gradient [29]) may end up in local minima, and that some technique for global optimization is needed. However, popular global optimizers based on stochastic frameworks such as simulated annealing [30] and genetic algorithms [31] converge too slowly to be successfully exploited in realistic applications.

Our approach to finding global minima of (3) utilizes physics-based *multiresolution*, conceptually analogous to what in the optimization community is known as the *continuation method* [32]. The basic idea underlying continuation methods is illustrated in Fig. 5, with reference to a simple one-dimensional problem. Once a suitable smoothing parameter in the function to be minimized has been recognized, a smoothing procedure is applied in order to filter out the unwanted local minima. A standard descent minimization algorithm can be applied to the smoothed problem, yielding a rough estimation of the sought global minimum of the original problem. The smoothing is progressively relaxed, restoring the original problem, and the solution is progressively refined, using at each stage a standard descent optimizer and exploiting as initial guess the estimation obtained at the previous stage.

As typical of many inverse scattering problems, the smoothness of the cost functional (3) strongly depends on the choice of operating wavelength(s). In particular, using larger wavelengths (i.e., lower frequencies) will result in a smoother functional. Furthermore, using lower frequencies reduces the possibility of phase ambiguity, one of the major causes of local minima. As an example, in Fig. 6 is shown the reduced 2D cost function obtained using the same simulation parameters as in Fig. 4, but only the longer wavelength ($\lambda_1 = 0.2$) data. The resulting function is considerably smoother. The function still has a global minimum at $(c_2, c_6) \approx (c_2^{(true)}, c_6^{(true)})$ with a large basin of attraction, and *no* local minima. In this case, standard descent optimizers (e.g. conjugate gradient [29]) can be applied. The obtained estimate will need refining at other frequencies for two reasons: at lower frequencies, *i*) a *poorer* resolution can be expected, and *ii*) the accuracy of the beam forward solver is *poorer* [11]. Nonetheless, this first estimate provides a good initial guess that can be further refined through progressively introducing the higher-frequency information into the optimization, in the spirit of the continuation method [32]. The proposed multiresolution strategy can be thus viewed as a continuation method, where the

smoothing parameters are the weight coefficients α_{pq} associated with the different wavelengths. Among all possible ways of varying the weight coefficients α_{pq} , which corresponds to different ways of controlling the smoothing and the convergence behavior, we chose the simplest, i.e., an abrupt “on-off” variation. At each resolution stage, the frequency data to be included in the cost functional are selected by setting the corresponding weight coefficients α_{pq} to 0 or 1. This corresponds to what in the inverse scattering community is usually known as *frequency hopping* [16]–[18].

In our implementation, the partial optimization at each resolution level is performed using the Polak-Ribiere version of the conjugate gradient (CG) algorithm [29], particularly suited for non-quadratic functions. Specifically, the needed gradient of J is computed using a central difference formula, so that each gradient evaluation requires $2N_h + 8$ functional evaluations (i.e., $2N_h + 8$ solutions of a forward scattering problem), $N_h + 4$ being the number of unknown spline coefficients. The CG algorithm in [29] has been partially modified in order to enforce the consistency constraint

$$\max_x \{h(x)\} < z_A, z^r, \quad (9)$$

where z_A and z^r are the aperture and observation heights, respectively (see Fig. 1).

IV. NUMERICAL RESULTS

In order to test our surface profile estimation algorithms, we generated synthetic field measurement data using a reliable full-wave solution of the forward scattering problem by means of the multifilament current method in [26], in conjunction with rigorous Kirchhoff aperture integration [33], for a variety of surfaces. For all numerical experiments presented below, the accuracy of the NW-GB forward solver was preliminarily verified. The simulation parameters are summarized in Fig. 3, with the dielectric half-space constitutive parameters chosen so as to simulate a class of sandy soils in the GPR frequency range. In this example, there are 16 unknown spline coefficients to be estimated, based on 40 complex (magnitude and phase) field samples. Reconstruction results are shown in Fig. 7. Assuming as initial guess a flat interface ($c_n = 0$, $n = -4, \dots, N_h - 1$), the cost functional (3) was minimized using only the lowest frequency data ($\lambda_1 = 0.2$), obtaining the recon-

struction shown in Fig. 7a. Subsequent refinements of this reconstruction were obtained by including higher frequency data, resulting in the improved approximations shown in Figs. 7b-d. Specifically, each iterative improvement in Figs. 7b-d is obtained by using only a *single frequency* at a time, and exploiting the reconstruction at the previous (lower) frequency as initial guess. The more time-consuming alternative of using at each iteration the *current frequency plus* the lower ones was found not to yield significant improvement. The example illustrates that the reconstruction is accurate throughout most of the interval, except near the edges of the illuminated region; a similar phenomenon was observed in [8]. The likely explanation for this loss of accuracy is due to the weak illumination in these regions, corresponding to the aperture field tapering; the tapering is required to avoid numerical artifacts attributed to edge effects.

We performed a thorough calibration of the proposed inversion algorithm, by reconstructing a large number of randomly generated surface realizations with moderate roughness both in height and slope ($\lesssim 40^\circ$). Representative results are shown in Fig. 8. For all examples we used the four-stage frequency-hopping scheme as in Fig. 7. Again, except near the edge regions, the reconstructions are quite accurate. As a general comment, we found satisfactory reconstructions for problem parameters (roughness, permittivity, etc.) in the range of validity of the forward model summarized in Sec. III-B.

We also investigated the numerical stability of the algorithm with respect to errors in the reflected field simulated/measured data. In order to simulate the unavoidable measurement uncertainty, we added to the full-wave-computed reflected field data a uniformly distributed relative error. Furthermore, in order to roughly simulate the effect of possible clutter sources neglected in the model, such as the incoherent scattering contribution from fine-scale roughness, we added a background noise with uniformly distributed amplitude and phase. Reconstruction results are shown in Fig. 9, with the problem parameters as in Fig. 3. As one can see, the reconstruction obtained from corrupted data with a relative error of $\pm 5\%$ in amplitude and $\pm 10^\circ$ in phase, and a background noise of -20 dB, is not very different (apart from the edge regions) from that obtained using noise-free data, thus indicating the robustness of the proposed algorithm. Increasing the noise strength obviously results in a poorer reconstruction, especially in the edge regions whose *weaker*

scattering contribution is more noise-sensitive. It is interesting to notice that even with a considerably stronger background noise (-10 dB), the reconstruction of the central region of the interface profile is still relatively accurate.

Concerning the convergence rate, in the above examples an average number of $20 - 30$ conjugate gradient iterations per resolution stage was typically required, resulting in an overall computing time of ~ 1 min. on a 500 MHz PC; no particular effort was made to optimize the numerical code.

V. CONCLUSIONS

We presented a new inversion algorithm for the reconstruction of moderately rough dielectric interfaces using spatially sampled (multifrequency) reflected field data. The proposed approach is based on a compact parameterization of the unknown interface profile in terms of quartic splines, whose unknown parameters are estimated by minimizing the *difference* between model-based and measured reflected field data. The approach uses a fast forward model based on quasi-ray Gaussian beams [11]. In order to avoid local minima, a frequency hopping multiresolution approach is used, exploiting reconstructions based only on longer wavelengths to provide initial guesses for higher resolution reconstructions.

The proposed algorithm was evaluated on noisy data generated from simulated profiles, illustrating that accurate and robust reconstructions can be obtained for moderate roughness (maximum slopes $\lesssim 40^\circ$), with reasonable computing times. Thus, extensions of the algorithmic approach to three-dimensional (3D) geometries should be feasible for realistic situations where sparse (multifrequency) data and limited computing resources are available, and near real-time estimates are required.

The approach presented in this paper is similar in spirit to that of [8], although based on a different forward solver and optimization schemes. In particular, our approach generalizes naturally to sparsely sampled data.

The surface estimation algorithm has been extended to time dependent (short pulse) GPR excitation [25], and has been incorporated into adaptive techniques for subsurface GPR image reconstruction of shallowly buried plastic mine-like targets in the presence of unknown rough air-soil interfaces [19]–[22]; preliminary outcomes seem encouraging. Extensions presently under investigation include generalization to fully 3D geometries.

Abstract

This paper deals with the short-pulse radiation of three-dimensional (3D) vector electromagnetic fields from arbitrarily polarized large two-dimensional (2D) truncated aperture distributions, which are parameterized in terms of narrow-waisted ray-like pulsed Gaussian basis beams centered on a discretized Gabor lattice in a four-dimensional configuration-spectrum phase space. The study extends our previous Gabor-based investigation of time domain (TD) short-pulse radiation of 2D fields from 1D large truncated apertures with nonphased, linearly phased (delayed) and nonlinearly phased focusing aperture field profiles [1]. We begin with, and summarize, a Gabor-based frequency domain (FD) formulation of the 2D aperture problem which has been presented and tested elsewhere [2], [3], but we include additional numerical examples for validation and quality assessment. As in [1], we access the time domain by Fourier inversion from the FD, starting from the initial 3D space-time Kirchhoff formulation (whose numerical integration furnishes reference solutions), and then passing on to Gabor-parameterized field representations in terms of pulsed beam (PB) wavepackets which are launched by linearly and nonlinearly phase-delayed focusing aperture distributions. Example calculations and comparisons with numerically generated reference data serve to calibrate the Gabor-PB algorithms and assess their domains of validity.

Keywords

Gaussian beams, pulsed beam wavepackets, Gabor lattice representations.

I. INTRODUCTION

In an ongoing series of recent investigations, we have revisited a previously formulated discretized Gabor-based narrow-waisted Gaussian beam (GB) algorithm for two-dimensional (2D) time-harmonic high-frequency radiation from truncated 1D planar aperture distributions [4], which was then applied to the interaction of these GB-parameterized radiated fields with complex propagation environments [5], [6]. The algorithm had been found to be robust, accurate, physically appealing, and numerically efficient when compared with conventional Kirchhoff Physical Optics integration procedures. Our recent interest has been motivated in part by the need of robust forward solvers in forward and inverse scattering (identification and imaging) scenarios concerned with objects embedded within an irregularly bounded penetrable semi-infinite medium. In a stepwise approach toward constructing the necessary algorithms, we have proceeded along two parallel routes: 1. extension of the frequency domain (FD) algorithms for the 1D aperture/2D field configuration to the new rough interface propagation environment, and to the new general case of 2D aperture/3D vector fields; 2. extension of the FD results to the short-pulse-excited

time domain (TD). The FD interaction of the 1D aperture radiated field with a moderately rough interface has been addressed in [7] and [8] for the forward problem and in [9] and [10] for the inverse problem, whereas the 2D aperture/3D field radiation problem has been addressed in [2] and [3]. The TD extension of the 1D aperture problem has been carried out in [1], and the extension to 2D apertures is the subject of the present paper. The contents of this paper having been summarized in the abstract, we pass on directly to the problem formulation and its solution via the Gabor-based narrow-waisted beam algorithm.

II. FORMULATION OF THE PROBLEM

We consider the radiation of three-dimensional (3D) vector electromagnetic (EM) fields excited by pulsed arbitrarily polarized extended two-dimensional (2D) vector field distributions in a truncated planar aperture of characteristic dimension d_A on the $z = 0$ plane of Fig. 1. We shall only deal with the vector electric field $\mathbf{e}(\mathbf{r}, t)$, $\mathbf{r} = x\mathbf{u}_x + y\mathbf{u}_y + z\mathbf{u}_z$; the vector magnetic fields can be derived from Maxwell's equations. Here and henceforth, bold face symbols denote vector quantities, and \mathbf{u}_α denotes a unit vector in the α -direction. The 2D space-time aperture field distribution will be specified as

$$\mathbf{e}_0(x, y, z = 0, t) = \mathbf{f}(x, y, t), \quad (x, y) \in \Gamma_A, \quad \mathbf{u}_z \cdot \mathbf{f} = 0. \quad (1)$$

The corresponding field radiated into the halfspace $z > 0$ can be obtained by space-time superposition, using the 3D time-domain (TD) Green's function

$$g_{3D}(\mathbf{r}, t; \mathbf{r}'_0, t') = \frac{\delta(t - t' - R/c)}{4\pi R}, \quad R = |\mathbf{r} - \mathbf{r}'_0|, \quad (2)$$

where $\mathbf{r}'_0 = x'\mathbf{u}_x + y'\mathbf{u}_y$, $\delta(\cdot)$ represents the Dirac delta function, and c is the ambient propagation speed. The subscript “ $_0$ ” identifies quantities in the $z = 0$ plane. The resulting field radiated into the halfspace $z > 0$, synthesized by superposition of point source contributions (Kirchhoff integration), is given by [11, p. 175]

$$\mathbf{e}(\mathbf{r}, t) = -\frac{1}{2\pi} \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} (\mathbf{r} - \mathbf{r}'_0) \times \left\{ \mathbf{u}_z \times \left[\frac{\mathbf{f}(x', y', t - R/c)}{R^3} + \frac{1}{cR^2} \frac{\partial}{\partial t} \mathbf{f}(x', y', t - R/c) \right] \right\} dx' dy'. \quad (3)$$

In Sec. IV-D, we shall be using a reference solution based on Gaussian quadrature numerical integration [12] of (3). In what follows, the time domain is accessed by Fourier inversion from the frequency domain (FD) via the Fourier transform pair

$$\mathbf{e}(\mathbf{r}, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \mathbf{E}(\mathbf{r}, \omega) \exp(-i\omega t) d\omega, \quad \mathbf{E}(\mathbf{r}, \omega) = \int_{-\infty}^{\infty} \mathbf{e}(\mathbf{r}, t) \exp(i\omega t) dt. \quad (4)$$

Capital letters identify FD field quantities.

III. RELEVANT FD RESULTS

This section contains a brief summary of relevant frequency domain (FD) results from [2], [3] and some new additions. The FD aperture field corresponding to (1) has an implicit $\exp(-i\omega t)$ time dependence and a spatial distribution $\mathbf{F}(x, y, \omega)$ (related to \mathbf{f} via the Fourier transform pair in (4)) over the aperture Γ_A in Fig. 1,

$$\mathbf{E}_0(x, y, z = 0, \omega) = \mathbf{F}(x, y, \omega), \quad (x, y) \in \Gamma_A, \quad \mathbf{u}_z \cdot \mathbf{F} = 0. \quad (5)$$

The resulting electric field in the halfspace $z > 0$, obtained by point-source (Kirchhoff) integration in configuration space, is given by [11, p. 107]

$$\mathbf{E}(\mathbf{r}, \omega) = 2 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \nabla G_{3D}(\mathbf{r}, \mathbf{r}'_0; \omega) \times [\mathbf{u}_z \times \mathbf{F}(x', y', \omega)] dx' dy', \quad (6)$$

where

$$G_{3D}(\mathbf{r}, \mathbf{r}'_0; \omega) = \exp(ikR)/(4\pi R), \quad R = |\mathbf{r} - \mathbf{r}'_0|, \quad (7)$$

is the 3D free-space FD Green's function, with $k = \omega/c = 2\pi/\lambda$ as the ambient wavenumber and λ as the wavelength. It can easily be verified (see [11, p. 175]) that $\mathbf{e}(\mathbf{r}, t)$ in (3) and $\mathbf{E}(\mathbf{r}, \omega)$ in (6) are related through the Fourier transform pair (4). In the remainder of this section, the ω dependence in \mathbf{E} and \mathbf{F} will be omitted for simplicity of notation, and the discussion relies heavily on references [1]–[3], with precise citations attached to each of the results extracted from these papers. Notationally, we use (2.5) to identify eqn. (5) in ref. [2], for example. We also call attention to the following differences between [2], [3] and the present paper: 1. [2] and [3] deal with the calculation of the vector potential \mathbf{P} whereas here we calculate the vector field \mathbf{E} . 2. The aperture potential field in [2] and [3]

is denoted by \mathbf{f} which should not be confused with the TD \mathbf{f} in (1) here. These differences do not affect the *basic format* of the Gabor expansions to which the citations refer.

A. Discretized Gabor-Based Field Representations in the Configuration-Spectrum Phase Space

A.1 Aperture Field

The vector aperture field $\mathbf{F}(x, y)$ can be expressed in the 2D Gabor Gaussian beam (GB) basis as follows (see (2.4))

$$\mathbf{F}(x, y) = \sum_{m,n,p,q=-\infty}^{\infty} \mathbf{A}_{mnpq} w(x - mL_x, y - pL_y) \exp[i(n\beta_x x + q\beta_y y)], \quad (8)$$

with $w(x, y)$ representing the normalized 2D Gaussian window in (2.10a),

$$w(x, y) = \left(\frac{2}{L_x L_y} \right)^{1/2} \exp \left\{ -\pi \left[(x/L_x)^2 + (y/L_y)^2 \right] \right\}, \quad \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} w^2(x, y) dx dy = 1. \quad (9)$$

The representation in (8) is tied to a four-dimensional lattice in the $(x, y; k_x, k_y)$ phase-space (Fig. 2), k_x, k_y being the x and y -domain wavenumbers, respectively, which can be expressed in terms of the spherical polar coordinate angles θ, ϕ (see Fig. 1) as

$$k_x = k \sin \theta \cos \phi, \quad k_y = k \sin \theta \sin \phi, \quad k_z = \sqrt{k^2 - k_x^2 - k_y^2} = k \cos \theta. \quad (10)$$

In this Gabor basis, each lattice point locates a Gaussian beam, whose initial profile matches the corresponding basis function. Indexes (m, p) tag x, y spatial shifts, respectively, whereas (n, q) tag k_x, k_y spectral shifts (i.e., beam tilts θ_{nq}, ϕ_{nq}), respectively. Spatial and spectral periods are related by the self-consistency relation (configuration-spectrum tradeoff) (2.4a),

$$L_x \beta_x = L_y \beta_y = 2\pi. \quad (11)$$

From (10), as the spectral shifts increase, the corresponding (n, q) beam polar angles $\theta_{nq} = \sin^{-1}[(k_x^2 + k_y^2)^{1/2}/k]_{nq}$, i.e.,

$$\theta_{nq} = \sin^{-1} \left[\frac{\sqrt{(n\beta_x)^2 + (q\beta_y)^2}}{k} \right] = \sin^{-1} \left[\sqrt{\left(\frac{n\lambda}{L_x} \right)^2 + \left(\frac{q\lambda}{L_y} \right)^2} \right], \quad (12)$$

become *complex* for $[(n\lambda/L_x)^2 + (q\lambda/L_y)^2] > 1$, and therefore the corresponding beams away from the aperture (see Sec. III-A.2) become *evanescent*. In the second equality of (12), use has been made of (11) and $k = 2\pi/\lambda$.

The expansion coefficients in (8) can be computed by introducing an auxiliary *bi-orthogonal* function $\gamma(x, y)$ (cf. (2.8)),

$$\mathbf{A}_{mnpq} = \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \mathbf{F}(x, y) \gamma^*(x - mL_x, y - pL_y) \exp[-i(n\beta_x x + q\beta_y y)] dx dy, \quad (13)$$

where * denotes the complex conjugate. For the Gaussian window in (9), a closed-form expression for $\gamma(x, y)$ is derived in [2, App. C]. Alternatively, the Gabor coefficients can be computed effectively by schemes employed in image processing [13]. However, we shall avoid this calculation later on by specializing to narrow-waisted Gaussian basis functions (see Sec. III-B).

A.2 Radiated Field

The Gabor lattice representation for the field radiated into the halfspace $z > 0$ follows by combining (6) and (8),

$$\mathbf{E}(\mathbf{r}) = \sum_{m,n,p,q=-\infty}^{\infty} (\mathbf{A}_{mnpq} \times \mathbf{u}_z) \times \mathbf{B}_{mnpq}(\mathbf{r}), \quad (14)$$

with the (vector) beam propagator \mathbf{B}_{mnpq} expressed by Gabor-weighted point-source superposition as

$$\mathbf{B}_{mnpq}(\mathbf{r}) = 2 \int_{-\infty}^{\infty} \int_{-\infty}^{\infty} \nabla G_{3D}(\mathbf{r}, \mathbf{r}_0) w(x' - mL_x, y' - pL_y) \exp[i(n\beta_x x' + q\beta_y y')] dx' dy'. \quad (15)$$

B. Narrow-Waisted Beams

When the observer is located in the *paraxial far-zone* of a beam, the integral in (15) can be evaluated by saddle-point asymptotics. It is shown in [3, Sec. III], that the result can be

expressed in an explicit closed form in terms of *complex source point* (CSP) propagators, provided the beams are nontilted ($n = q = 0$), narrow-waisted ($L_{x,y} \lesssim \lambda \ll d_A$), and distributed over a symmetric lattice ($L_x = L_y = L$). Narrow-waisted (ray-like) GBs have been shown in a series of previous studies of 2D fields excited by 1D apertures [5]–[8] to yield highly efficient and accurate algorithms for synthesis of interactions with complex propagation and scattering environments. The narrow-waisted nontilted GB can be related to the 3D-CSP Green’s function \tilde{G}_{3D} as follows (cf. (3.14))

$$\tilde{\mathbf{B}}_{m0p0}(\mathbf{r}) \sim 2\sqrt{2}L \exp(-kb) \nabla \tilde{G}_{3D}(\mathbf{r}, \tilde{\mathbf{r}}'_{mp}) \quad (16)$$

$$\sim ikL \frac{\exp[ik(\tilde{R}_{mp} + ib)]}{\sqrt{2\pi}\tilde{R}_{mp}^2} (\mathbf{r} - \tilde{\mathbf{r}}'_{mp}), \quad (17)$$

where

$$\tilde{R}_{mp} = |\mathbf{r} - \tilde{\mathbf{r}}'_{mp}| = \sqrt{(x - x'_m)^2 + (y - y'_p)^2 + (z - \tilde{z}')^2}, \quad \text{Re}(\tilde{R}_{mp}) \geq 0, \quad (18)$$

is the complex distance between the real observation point \mathbf{r} and the complex source point

$$\tilde{\mathbf{r}}'_{mp} = x'_m \mathbf{u}_x + y'_p \mathbf{u}_y + \tilde{z}' \mathbf{u}_z = mL \mathbf{u}_x + pL \mathbf{u}_y + ib \mathbf{u}_z. \quad (19)$$

Here and henceforth the tilde \sim identifies dependence on analytically continued spatial source coordinates as well as the field produced thereby. The complex displacement parameter is given by (3.11c),

$$\tilde{z}' = ib, \quad b = L^2/\lambda; \quad (20)$$

one notes that b is the beam Fresnel length corresponding to an “effective” beam waist L . Equations (16) and (17) are valid in the paraxial far-zone of each beam, $|\tilde{R}_{mn}| \gg b$, and are restricted to symmetric and nontilted beams only. However, recalling (12), one observes that these nontilted sufficiently *narrow* beams with $n = q = 0$, $L \lesssim \lambda \ll d_A$, yield the dominant contribution to the radiated field because all other beams are evanescent.

An important attractive feature of narrow-waisted GBs is that their Gabor coefficients can be estimated effectively by *aperture sampling* (see (3.19)), avoiding the time-consuming operations required in (13) and (2.11a,b) or [13],

$$\mathbf{A}_{mpq} \approx \begin{cases} (L/\sqrt{2})\mathbf{F}(mL, pL), & n, q = 0, \\ 0, & n, q \neq 0, \end{cases} \quad (21)$$

so that

$$\tilde{\mathbf{E}}(\mathbf{r}) \sim \sum_{m,p} (\mathbf{A}_{m0p0} \times \mathbf{u}_z) \times \tilde{\mathbf{B}}_{m0p0}(\mathbf{r}). \quad (22)$$

Due to the finite extent of the aperture, the (m, p) summations in (22) include only a finite number of beams, given roughly by $(d_A/L)^2$. The approximation in (21) and (22) neglects the tilted $(n, q \neq 0)$ beams in the Gabor expansion which, however, are *evanescent* for $[(n\lambda/L_x)^2 + (q\lambda/L_y)^2] > 1$, as noted earlier. Subject to the constraints $n = q = 0$, $L \lesssim \lambda \ll d_A$, the CSP paraxial *far-zone* approximation (17) can be invoked at *moderate* distance, within and beyond the radiating *near-zone* of the *aperture*. The resulting beam synthesis in (22), with (21) and (17), yields an efficient algorithm which has been tested and validated in Sec. III-D.

C. Linearly Phased Aperture

For linearly-phased distributions, the aperture field becomes

$$\mathbf{F}(x, y) = \mathbf{g}(x, y) \exp[ik \sin \theta_A (x \cos \phi_A + y \sin \phi_A)], \quad (23)$$

where $\mathbf{g}(x, y)$ is a real function and θ_A, ϕ_A specify the direction of the main radiation lobe. Now, a more effective implementation of the narrow-waisted beam discretization can be achieved by exploiting *propagation-matched tilted* beams, which has not been investigated in [3]. As for the 2D field/1D aperture problem in [1], this is achieved by Gabor-expanding the real function $\mathbf{g}(x, y)$ only, and including the linear phasing in the beam integral (15) for the \mathbf{B}_{m0p0} beam propagator. Accordingly, generalizing the 1D aperture expressions in (1.18)–(1.20) to the 2D aperture case, the narrow-waisted beam expansion (22) can be recast as (for simplicity, the subscript “ $m0p0$ ” is henceforth replaced by “ mp ”)

$$\tilde{\mathbf{E}}(\mathbf{r}) \sim \sum_{m,p} (\mathbf{C}_{mp} \times \mathbf{u}_z) \times \tilde{\mathbf{B}}_{mp}(\mathbf{r}), \quad (24)$$

where

$$\mathbf{C}_{mp} \approx (L/\sqrt{2})\mathbf{g}(mL, pL), \quad (25)$$

$$\tilde{\mathcal{B}}_{mp}(\mathbf{r}) = ikL \frac{\exp[ik(\tilde{R}_{mp} + ib + \mathcal{L}_{mp})]}{\sqrt{2\pi}\tilde{R}_{mp}^2} (\mathbf{r} - \tilde{\mathbf{r}}'_{mp}), \quad (26)$$

$$\mathcal{L}_{mp} = L \sin \theta_A (m \cos \phi_A + p \sin \phi_A), \quad (27)$$

$$\tilde{R}_{mp} = |\mathbf{r} - \tilde{\mathbf{r}}'_{mp}|, \quad (28)$$

$$\begin{aligned} \tilde{\mathbf{r}}'_{mp} &= \tilde{x}'_m \mathbf{u}_x + \tilde{y}'_p \mathbf{u}_y + \tilde{z}' \mathbf{u}_z = \\ &= (mL + ib \sin \theta_A \cos \phi_A) \mathbf{u}_x + (pL + ib \sin \theta_A \sin \phi_A) \mathbf{u}_y + ib \cos \theta_A \mathbf{u}_z, \end{aligned} \quad (29)$$

$$b = (L \cos \theta_A)^2 / \lambda. \quad (30)$$

Instead of \mathbf{A}_{mp} , \mathbf{C}_{mp} in (24) and (25) identifies Gabor coefficients associated with the tilt-matched linearly phased aperture formulation. The beam propagator (26) differs from $\tilde{\mathbf{B}}_{m0p0}$ in (17) by the phase shift ($ik\mathcal{L}_{mp}$) and by the different definitions of the CSP $\tilde{\mathbf{r}}'_{mp}$ and b in (29) and (30), respectively (see (1.21) and (1.22)), which produce the propagation-matched tilt (θ_A, ϕ_A) in the beam direction. Equation (26) can be obtained by the same procedure that leads to (17), or even by inspection, recalling the 1D aperture results [1]. As shown in Sec. III-D below, for linearly phased apertures, the tilted beam expansion (24) allows significantly coarser lattice sampling than (22), for the same degree of accuracy. For *moderately* nonlinear phasing it may still be convenient to split the phase function into a linear term (included in the beam propagator as above) and a nonlinear remainder (included in the Gabor-expanded function \mathbf{g}), but no particular benefit is expected for *strongly* nonlinear phasing (e.g., strongly focused apertures).

D. Numerical Results

In order to compare the nontilted and tilted formulations in (22) and (24), respectively, we consider the linearly phased distribution in (23), with an x -polarized tapered square cosine amplitude distribution

$$\mathbf{g}(x, y) = \begin{cases} \cos(\pi x/d_A) \cos(\pi y/d_A) \mathbf{u}_x, & |x|, |y| \leq d_A/2, \\ 0, & |x|, |y| > d_A/2. \end{cases} \quad (31)$$

It follows from (6) that the resulting vector electric field radiated into the $z > 0$ half-space has x, z components only. All other parameters used in our simulations are listed in the figure captions. In our simulations, we assume $\theta_A = 30^\circ$, $\phi_A = 45^\circ$, and a fixed (symmetric) beam lattice period ($L_x = L_y = L = 0.8\lambda$). In Figs. 3a and 3b, the x -components of the radiated fields synthesized under the same conditions with the same number ($(d_A/L)^2 \sim 150$) of narrow-waisted nontilted (22) and tilted (24) beams are compared with the reference solution (Gaussian quadrature numerical integration of (6)), showing representative x - and y -cuts, respectively, at a fixed value of z well within the aperture near-zone. The tilted beam synthesis is barely distinguishable from the reference solution, whereas the nontilted synthesis is noticeably more *inaccurate*. The accuracy is more clearly quantified in Figs. 3c and 3d, where the relative error magnitudes

$$\Delta E_{x,z} \equiv \frac{|E_{x,z}^{(ref)} - E_{x,z}^{(beam)}|}{\max |E_{x,z}^{(ref)}|}, \quad (32)$$

are displayed as gray-scale plots. It is observed that the tilted beam synthesis attains a maximum error $< -30\text{dB}$, whereas the nontilted beam synthesis error is evidently greater. In order to obtain comparable accuracy with nontilted beams, a considerably smaller beam lattice period ($L \sim 0.1\lambda$) should be used, resulting in an overall computation time increase of almost *two orders of magnitude*. The corresponding results for the z component are shown in Fig. 4, and the same considerations apply. The nonphased case ($\theta_A = 0$) yields the same results as in [3].

As a further more challenging test, we consider a *quadratically-phased*, cosine-tapered aperture field distribution

$$\mathbf{F}(x, y) = \mathbf{g}(x, y) \exp \left[-ik \frac{(x^2 + y^2)}{2L_f} \right], \quad (33)$$

with $\mathbf{g}(x, y)$ defined in (31), which produces focusing ($L_f > 0$) or defocusing ($L_f < 0$), with L_f representing the conventional focal length. Figure 5a shows the magnitude profile plot of the x component of radiated electric field at the focal plane $z = L_f > 0$ (chosen well within the aperture near-zone), computed via numerical Kirchhoff integration of (6). The wavefield is peaked around the point $(x, y) = (0, 0)$, clearly highlighting the focusing effects. Figures 5b and 5c show representative x - and y -cuts, respectively, where the reference solutions are compared with the narrow-waisted beam synthesis (22). Note that, as compared with the linearly phased example, a smaller beam lattice period with a correspondingly larger number of beams ($(d_A/L)^2 = 2500$) is required for the strongly nonlinear phasing in order to attain comparable accuracy. As shown in Fig. 5d, a value $L = 0.2\lambda$ suffices to keep the maximum error below -30dB . The corresponding results for the z component are shown in Fig. 6, and the same conclusions hold. It should be emphasized that the near-zone focal plane field poses a relatively strong challenge; for moderate observation distances away from the focal plane, a coarser discretization is adequate.

IV. TD FORMULATION

A. TD Narrow-Waisted Beam Discretization: Linear-Delay Aperture Fields

Rigorous extension, into the time domain (TD), of the Gaussian beam discretization for the time-harmonic aperture distribution in Sec. III would require a six-index Gabor series tied to a discretized lattice in the 6D (space-time, wavenumber-frequency) phase space. However, for the narrow-waisted beams in Sec. III-B, which we shall use throughout, implementation of the Gabor algorithm simplifies substantially. In particular, we extend the TD formulation for 2D field radiation by 1D pulsed aperture distributions in [1] to pulsed radiation from 2D aperture distributions. As in [1, Sec. III-A], generalizing (1.28), we first consider space-time separable aperture fields with linear time delay and θ_A, ϕ_A real,

$$\mathbf{f}(x, y, t) = \mathbf{g}(x, y)p[t - c^{-1} \sin \theta_A(x \cos \phi_A + y \sin \phi_A)], \quad (34)$$

and its FD counterpart via (4),

$$\mathbf{F}(x, y, \omega) = P(\omega)\mathbf{g}(x, y) \exp[ik \sin \theta_A(x \cos \phi_A + y \sin \phi_A)]. \quad (35)$$

Here, $p(t)$ is a pulse of short length with respect to the characteristic aperture width d_A , i.e., $T \ll d_A/c$, and $P(\omega)$ is its Fourier transform,

$$P(\omega) = \int_{-\infty}^{\infty} p(t) \exp(i\omega t) dt. \quad (36)$$

The results in this section are related to those in Sec. III through the Fourier transform in (4) filtered by the pulse spectrum $P(\omega)$. When the aperture field is expressed in the Gabor representation based on the CSP beam propagator in (26), the presence of its evanescent spectra motivates use of the one-sided analytic transform [11, p. 222] as in [1],

$$f^+(t) = \frac{1}{\pi} \int_0^{\infty} F(\omega) \exp(-i\omega t) d\omega, \quad \text{Im}(t) \leq 0, \quad (37)$$

where $F(\omega)$ is the conventional Fourier spectrum of the real signal $f(t)$ (see (4)), and the real signal for real t is recovered via

$$f(t) = \text{Re} \left[f^+(t) \right]. \quad (38)$$

Then by FD inversion of (24),

$$\mathbf{e}^+(\mathbf{r}, t) \sim \sum_{m,p} (\mathbf{c}_{mp} \times \mathbf{u}_z) \times \mathbf{b}_{mp}^+(\mathbf{r}, t), \quad (39)$$

with $\mathbf{c}_{mp} = \mathbf{C}_{mp}$ in (25), and the analytic pulsed beam (PB) propagator \mathbf{b}_{mp}^+ expressed via (37) in terms of the paraxial, far-zone FD propagator $\tilde{\mathcal{B}}_{mp}$ in (26) as

$$\mathbf{b}_{mp}^+(\mathbf{r}, t) = \frac{1}{\pi} \int_0^{\infty} \tilde{\mathcal{B}}_{mp}(\mathbf{r}, \omega) P(\omega) \exp(-i\omega t) d\omega, \quad \text{Im}(t) \leq 0. \quad (40)$$

To simplify the evaluation of the integral in (40), it has been customary to choose the complex displacement ib in (26) to be frequency independent so as to yield “isodiffracting”

basis beam wavepackets which remain collimated over a range of frequencies [14]. Via (30), the isodiffracting excitation requires a frequency-dependent beam lattice. However, as noted before (see also [1]), this leads to frequency-dependent Gabor coefficients which cannot be computed by aperture profile sampling when the narrow-waisted constraint is imposed. We therefore choose L to be frequency independent, to obtain the approximate Gabor coefficients

$$\mathbf{c}_{mp} = \mathbf{C}_{mp} \approx (L/\sqrt{2})\mathbf{g}(mL, pL), \quad (41)$$

but at the expense of a frequency-dependent b , which is dealt with below. From here on, we continue by generalizing the 1D aperture algorithm in [1], and consider a class of differentiated Gaussian pulses (cf. (1.37) and (1.38)),

$$p(t) = P_0 p_g^{(j)}(t - T/2, T), \quad (42)$$

$$P(\omega) = P_0 (-i\omega)^j \exp(i\omega T/2) P_g(\omega, T), \quad (43)$$

where P_0 is a normalization constant, the superscript $^{(j)}$ indicates j -th order differentiation with respect to t , and $p_g(t)$, $P_g(\omega)$ denote the standard Gaussian pulse and its spectrum, respectively,

$$p_g(t, T) = \exp \left[- \left(\frac{t}{\sigma T} \right)^2 \right], \quad P_g(\omega, T) = \sqrt{\pi} \sigma T \exp \left(- \frac{\sigma^2 T^2 \omega^2}{4} \right); \quad (44)$$

the variance σ is chosen so that the pulse width of $p(t)$ is $\sim T$.

To de-emphasize the effect of the frequency-dependent parameter b on the complex distance \tilde{R}_{mp} in (28), we assume L/λ (and therefore b) sufficiently small, so that the resulting amplitude factor in the FD beam propagator (26) can be approximated by (see (29) or (1.39))

$$\frac{\mathbf{r} - \tilde{\mathbf{r}}'_{mp}}{\tilde{R}_{mp}} \approx \frac{\mathbf{r} - \mathbf{r}'_{mp}}{R_{mp}}, \quad \mathbf{r}'_{mp} = mL\mathbf{u}_x + pL\mathbf{u}_y, \quad R_{mp} = |\mathbf{r} - \mathbf{r}'_{mp}|, \quad b/L = L(\cos \theta_A)^2/\lambda \ll 1, \quad (45)$$

where the source point \mathbf{r}'_{mp} and the distance R_{mp} are now *real* and *frequency independent*. In the phase, under the same assumptions, we retain the first order paraxial correction (extending (1.40)),

$$\tilde{R}_{mp} \approx z_{bmp} - ib + \frac{\rho_{bmp}^2}{2(z_{bmp} - ib)} \approx z_{bmp} - ib + \frac{\rho_{bmp}^2(z_{bmp} + ib)}{2z_{bmp}^2}, \quad (46)$$

subject to (see (1.42) and (1.43))

$$|z_{bmp} - ib| \gg \rho_{bmp}, \quad b = \frac{(L \cos \theta_A)^2 \omega}{2\pi c} \ll z_{bmp}, \quad \omega \leq \Omega. \quad (47)$$

Here, $\rho_{bmp} = (x_{bmp}^2 + y_{bmp}^2)^{1/2}$, Ω denotes the bandwidth of the pulse spectrum $P(\omega)$, and $(x_{bmp}, y_{bmp}, z_{bmp})$ are the 3D beam coordinates (cf. (1.41))

$$\begin{bmatrix} x_{bmp} \\ y_{bmp} \\ z_{bmp} \end{bmatrix} = \begin{bmatrix} \cos \theta_A \cos \phi_A & \cos \theta_A \sin \phi_A & -\sin \theta_A \\ -\sin \phi_A & \cos \phi_A & 0 \\ \sin \theta_A \cos \phi_A & \sin \theta_A \sin \phi_A & \cos \theta_A \end{bmatrix} \begin{bmatrix} x - mL \\ y - pL \\ z \end{bmatrix}. \quad (48)$$

Applying (45)–(48) to (26), the tilted beam propagator $\tilde{\mathcal{B}}_{mp}$ in (40) can be written concisely as

$$\tilde{\mathcal{B}}_{mp}(\mathbf{r}, \omega) \approx -\Lambda_{mp} i\omega \exp\left(-\frac{\omega^2 T_{mp}^2}{4} + i\omega \tau_{mp}\right) (\mathbf{r} - \mathbf{r}'_{mp}), \quad (49)$$

where

$$\Lambda_{mp}(\mathbf{r}) = -\frac{L}{\sqrt{2\pi c R_{mp}^2}}, \quad (50)$$

$$\tau_{mp}(\mathbf{r}) = c^{-1} \left[z_{bmp} + \frac{\rho_{bmp}^2}{2z_{bmp}} + L \sin \theta_A (m \cos \phi_A + p \sin \phi_A) \right], \quad (51)$$

$$T_{mp}(\mathbf{r}) = \frac{\rho_{bmp} L \cos \theta_A}{\sqrt{\pi c z_{bmp}}}. \quad (52)$$

In contrast with the 1D aperture problem [1], the beam propagator in (49) *does not* contain fractional powers of the frequency; therefore, for the class of pulses in (42)–(44), the PB propagator can be evaluated more easily. In particular, by substituting (43), (44)

and (49) into (40), and recalling basic properties (differentiation, time-shift) of analytic signals, one obtains

$$\mathbf{b}_{mp}(\mathbf{r}, t) = \text{Re} \left[\mathbf{b}_{mp}^+(\mathbf{r}, t) \right] = \frac{P_0 \Lambda_{mp} \sigma T}{\mathcal{T}_{mp}} p_g^{(j+1)} [(t - T/2 - \tau_{mp}) \sigma, \mathcal{T}_{mp}] (\mathbf{r} - \mathbf{r}'_{mp}), \quad (53)$$

$$\mathcal{T}_{mp} = \sqrt{T_{mp}^2 + \sigma^2 T^2}. \quad (54)$$

Thus, the analytic TD narrow-waisted beam expansion in (39) reduces to an efficiently computable closed form in terms of simple analytic functions, with the real field obtained from

$$\mathbf{e}(\mathbf{r}, t) = \text{Re} \left[\mathbf{e}^+(\mathbf{r}, t) \right] \sim \sum_{m,p} (\mathbf{c}_{mp} \times \mathbf{u}_z) \times \mathbf{b}_{mp}(\mathbf{r}, t), \quad (55)$$

Modulated Gaussian pulses can be treated similarly, but require a slightly more complex algebra involving error functions [15].

B. TD Narrow-Waisted Beam Discretization: Nonlinear-Delay Aperture Fields

We now extend the results in Sec. IV-A to the more general aperture field distribution (c.f. (1.52))

$$\mathbf{f}(x, y, t) = \mathbf{s}(x, y) p \left[t - c^{-1} \Phi(x, y) \right], \quad (56)$$

obtained by Fourier inversion of

$$\mathbf{F}(x, y, \omega) = P(\omega) \mathbf{s}(x, y) \exp \left[i \frac{\omega}{c} \Phi(x, y) \right], \quad (57)$$

where $\mathbf{s}(x, y)$ and $\Phi(x, y)$ are real functions. For moderately nonlinear phasing $\Phi(x, y)$, as discussed in Sec. III-C for the FD synthesis, it may be convenient to split the phase (delay) function into a linear part plus a nonlinear remainder

$$\Phi(x, y) = \sin \theta_A (x \cos \phi_A + y \sin \phi_A) + \Phi_{NL}(x, y), \quad (58)$$

where $\Phi_{NL}(x, y)$ does not contain linear terms. Referring to (23), $\mathbf{g}(x, y)$ is now given by

$$\mathbf{g}(x, y) = \mathbf{s}(x, y) \exp[ik\Phi_{NL}(x, y)], \quad (59)$$

with the *complex* Gabor coefficients (see (25)),

$$\mathbf{C}_{mp} = (L/\sqrt{2})\mathbf{s}(mL, pL) \exp[ik\Phi_{NL}(mL, pL)]. \quad (60)$$

The corresponding TD beam expansion differs slightly from (39) (see (1.57)),

$$\mathbf{e}(\mathbf{r}, t) \sim \sum_{m,p} (\mathbf{s}_{mp} \times \mathbf{u}_z) \times \mathbf{b}_{mp}(\mathbf{r}, t - t_{mp}), \quad (61)$$

with the PB propagator \mathbf{b}_{mp} taken from (53), and

$$\mathbf{s}_{mp} = (L/\sqrt{2})\mathbf{s}(mL, pL), \quad t_{mp} = c^{-1}\Phi_{NL}(mL, pL). \quad (62)$$

For strongly nonlinear phasing, the splitting in (58) offers no computational advantages over the *nontilted* version (i.e., $\theta_A = \phi_A = 0$ in (53)) applied to the entire phase function $\Phi(x, y)$.

C. Assessment of Accuracy

The explicit closed form expressions developed in Sec. IV-A for the beam propagator integral in (40) are based on a sequence of approximations which have been expressed in terms of interdependent inequalities that involve all relevant problem parameters and are stated in (45) and (47). To systematize estimates of the range of validity in this multiscale problem, it is useful to define a nondimensional (ND) estimator which embodies all of the problem parameters and is structured around specifically scaled ND parameter combinations containing quantities of special interest.

The most stringent overall constraint in (45) and (47) is the *smallness* of the beam parameter b over the whole bandwidth of interest (the second inequality in (47)), which actually determines the maximum allowable lattice period (i.e., the minimum number of beams) for specified Ω , θ_A , and observation point. For specified observation plane at $z = z_{obs}$, recalling that $z_{bmp} = z_{obs}/\cos\theta_A$, this constraint can be written as

$$\frac{(L \cos \theta_A)^2 \Omega}{2\pi c} \ll \frac{z_{obs}}{\cos \theta_A}. \quad (63)$$

Multiplying and dividing by $d_A^2 T$ on the right hand side, and introducing the auxiliary ND parameters

$$N_b = \left(\frac{d_A}{L} \right)^2 \quad (\text{number of beams in (39)}), \quad (64)$$

$$\kappa = \frac{\Omega T}{2\pi} \quad (\text{normalized bandwidth of the pulse}), \quad (65)$$

$$F_d = \frac{d_A^2}{cT} \quad (\text{Fresnel distance of the aperture}), \quad (66)$$

$$\chi = \frac{z_{obs}}{F_d}, \quad (\text{normalized distance from the aperture}), \quad (67)$$

the constraint in (63) can be written compactly in terms of the ND estimator Q ,

$$Q \equiv \frac{\kappa(\cos \theta_A)^3}{\chi N_b} \ll 1, \quad (68)$$

which highlights the important role of N_b in the algorithm architecture. Actually, except for square apertures, N_b does not represent the precise number of effective beams (i.e., those with nonzero Gabor coefficients) in the expansion (39), and it should be regarded as a conservative estimate. For robustness, it is required that the number of beams, N_b , is large enough to render the narrow-waisted beam synthesis insensitive to “scramblings” of the beam-lattice parameters, i.e., to different combinations of these parameters within the narrow-waisted constraint. With this in mind, one observes from (68), for example, that decreasing the number of beams N_b can be compensated for by a corresponding increase in χ , i.e., in the observation distance z_{obs} when F_d is specified. In principle, the ND estimator Q in (68) can be used for linear as well as non-linear delay aperture field distributions (see Sec. IV-D). However, the actual value of Q ensuring a prescribed accuracy may vary for different distributions. In particular, a finer discretization (i.e., larger N_b) is usually required in the presence of nonlinear phasing/delay, for the same degree of accuracy.

D. Numerical Results

Extensive numerical simulations have been performed in order to validate and calibrate the PB syntheses introduced in Secs. IV-A and IV-B. Here we have selected some rep-

representative results, comparing the beam syntheses with a reference solution obtained via Gaussian quadrature numerical integration [12] of (3). In all simulations, the aperture field distributions are assumed to be x -polarized and therefore (see (3)) the radiated fields contain only x, z components. The assumed temporal excitation is the wideband Rayleigh pulse (four-times differentiated Gaussian) shown in Fig. 7, obtained from (42)-(44) with

$$j = 4, \quad P_0 = T^4/30000, \quad \sigma = 1/\sqrt{50}. \quad (69)$$

The examples presented below represent the TD counterparts of the FD cases discussed in Sec. III-D. In all simulations, we used a pulse-bandwidth value $\Omega T = 40$ (see Fig. 7), which sets the reference level for the ND estimator Q .

We first consider the linear-delay aperture field distribution in (34), with $\mathbf{g}(x, y)$ taken as the x -polarized, cosine-tapered distribution in (31). Figure 8 shows typical results for the x -component of the radiated field for $\theta_A = 30^\circ, \phi_A = 45^\circ$. The problem parameters are listed in the caption. In Fig. 8a, a gray-scale snapshot of the reference field solution is observed in the near-zone of the aperture at a fixed value of z and ct . To highlight details of the PB synthesis in (55), various 1D cuts of the space-time wavefield are displayed in Figs. 8b–8d for a specified beam lattice period, and are compared with the reference solution. Excellent agreement has been obtained with a relatively small number (20×20) of beams (the two solutions are almost indistinguishable on the scale of the plots); the corresponding value of the nondimensional estimator in (68) is $Q \approx 0.1$. Similar results are observed for the z -component in Fig. 9. The convergence of the PB synthesis and the role of the nondimensional estimator Q are illustrated in Fig. 10, which displays as a function of Q the r.m.s. (energy) error $\Delta e_{x,z}$ at fixed observation points \mathbf{r} in the near, intermediate, and far zone of the aperture,

$$\Delta e_{x,z} \equiv \frac{\int_{-\infty}^{\infty} \left| e_{x,z}^{(ref)}(\mathbf{r}, t) - e_{x,z}^{(beam)}(\mathbf{r}, t) \right|^2 dt}{\left[\int_{-\infty}^{\infty} \left| e_{x,z}^{(ref)}(\mathbf{r}, t) \right|^2 dt \int_{-\infty}^{\infty} \left| e_{x,z}^{(beam)}(\mathbf{r}, t) \right|^2 dt \right]^{1/2}}. \quad (70)$$

Each curve in Fig. 10 refers to a fixed observation point, and is parameterized in terms of Q by varying the remaining free parameter in (68), i.e., the number of beams N_b . One observes that the error decreases almost monotonically with decreasing Q (i.e., increasing

N_b). Moreover, the error vs. Q is *weakly* dependent on the observation distance, confirming our previous experience that, for the same degree of accuracy, a coarser discretization can be used as the observation distance increases, subject to (68). Quantitatively, values of $Q \approx 0.1$ (as in Figs. 8 and 9) yield an error < -20 dB, which is usually acceptable.

As a final example, we consider an x -polarized, cosine tapered, aperture distribution with quadratic delay

$$\mathbf{f}(x, y, t) = \mathbf{g}(x, y)p \left[t + (x^2 + y^2)/(2cL_f) \right], \quad (71)$$

where $\mathbf{g}(x, y)$ is defined in (31). The above distribution represents the TD counterpart of the FD focusing/defocusing distribution in (33), and constitutes a particularly stringent test for the nonlinear-delay aperture PB synthesis in (61). Figure 11 contains representative results for the x -component of the radiated field, observed in the critical focal plane $z = L_f$ which has been chosen at moderate distance from the aperture, $L_f = 0.2F_d$. In particular, Fig. 11a shows a snapshot of the reference solution at the time instant $ct = 20.44$, where the focusing effects are clearly evident. The PB synthesis in (61), for a fixed value of the beam lattice period, is compared with the reference solution in a number of representative 1D cuts shown in Figs. 11b–11d, with excellent agreement. Similar observations apply to the z -component of the radiated field in Fig. 12. Note that standard (non-uniform) ray asymptotics would fail due to the presence of caustic transition regions. As in the FD case (cf. Sec. III-D), the narrow-waisted pulsed beams still yield an accurate wavefield synthesis, with an increase (in this example of a factor 16) in the computational effort, as compared with the linear-delay distributions. In this example, we used 80×80 beams, yielding $Q \approx 0.005$. The r.m.s. errors in (70) vs. Q are shown in Fig. 13 for various observation points. It is observed, for both components, that away from the focal plane $z = L_f$, the error and its numerical values behave similarly to those for the linear-delay case in Fig. 10. In particular, the error behavior is weakly dependent on the observation point. In the more critical focal plane, the error behavior is quite different: it is uniformly larger and reaches a plateau (< -20 dB) for $Q \lesssim 0.005$, indicating an intrinsic lower bound independent of the discretization. Such behavior was not observed in the FD, where the *full* CSP GB propagators are used, and therefore is probably related to the

paraxial approximation in (46), whose implications are not accounted for in the ND estimator Q (derived from (47)). For the moderate focusing in this example, this lower bound still yields reasonably accurate syntheses in the focal plane (see Figs. 11 and 12), but for considerably stronger focusing, decreased accuracy can be expected and has actually been encountered in numerical experiments. For these near-zone focal-plane field observations, our numerical simulations usually produced satisfactory accuracy ($\Delta e_{x,z} < -15\text{dB}$) for focused distributions with $L_f > 0.1F_d$. As seen from Fig. 13, reasonable accuracy can be achieved away from the focal plane within the $Q \lesssim 0.1$ constraint observed in the linear-delay-case.

The above beam syntheses were obtained with computing times ranging from 2ms (linearly-phased aperture with 400 beams in Figs. 8 and 9) to 32ms (focused aperture with 6400 beams in Figs. 11 and 12) per space-time sample on a 700 MHz PC. The reference solution was obtained via numerical quadrature of the Kirchhoff integration in (3), using a 7-point Gaussian formula [12] with discretization steps $\Delta_x = \Delta_y = d_A/350 = cT/35$, resulting in computing times of about 600 ms per space-time field sample.

V. CONCLUSIONS

Referring for background to the abstract and introduction (Sec. I), we have developed here a discretized Gabor-based narrow-waisted pulsed beam (PB) algorithm for synthesis of 3D vector fields radiated by truncated planar 2D aperture distributions with amplitude-tapered coordinate-separable linearly and nonlinearly phased profile functions. Building upon the frequency domain 2D aperture radiation analysis in [2], [3] and the time domain 1D aperture radiation study in [1], we have obtained the simple, readily computable, robust, explicit asymptotic PB expansions in (55) and (61). Calibration against reference solutions for a variety of numerical test configurations have established the accuracy and range of validity of the PB algorithms. The validity constraints have been formalized through the nondimensional estimator in (68), which combines all relevant problem parameters in terms of physically meaningful spatially and temporally scaled groupings. Computationally, the proposed PB syntheses appear attractive when compared with numerical Kirchhoff integrations, with typical computing times from about 20 to 300 times smaller.

Our next goal is the interaction of the radiated PBs with complex propagation environments. In this connection, forward and inverse scattering applications to 1D aperture/2D field configurations have been addressed in [16]–[18]. Extensions to 2D aperture/3D field configurations, by combining the PB discretization algorithm in the present paper with Kirchhoff Physical Optics techniques, are currently under consideration.

Abstract

We consider short-pulse (SP) time domain (TD) two-dimensional (2D) scattering by moderately rough dielectric interfaces excited by one-dimensional SP-TD aperture field distributions. This study extends to the SP-TD our previous investigation of time-harmonic *high frequency* 2D-scattering of Gabor-based quasi-ray Gaussian beam fields excited by 1D aperture field distributions in the presence of moderately rough dielectric interfaces [1]. The proposed approach is based on the Kirchhoff Physical Optics (PO) approximation in conjunction with the Gabor-based quasi-ray narrow-waisted Gaussian pulsed-beam (PB) discretization [2], which is applied to the equivalent induced SP “surface currents” on the interface that establish the TD reflected/transmitted fields. We show that, for well-collimated truncated SP incident fields, the PO-PB synthesis of the reflected/transmitted fields yields an approximate *explicit* physically appealing, numerically efficient asymptotic algorithm, with well-defined domains of validity based on the problem parameters. An extensive series of numerical experiments verifies the accuracy of our method by comparison with a rigorously based numerical reference solution. The algorithm is intended for use as a rapid forward solver in SP-TD inverse scattering and imaging scenarios in the presence of moderately rough dielectric interfaces.

Keywords

Rough surface scattering, Gaussian beams, short pulses.

I. INTRODUCTION

This paper is concerned with the short-pulse (SP) time domain (TD) scattering of two-dimensional (2D) fields by 1D moderately rough dielectric interfaces which separate two semi-infinite air and dielectric regions, respectively, and are excited by incident fields from SP planar 1D truncated aperture distributions. The aperture emits a well-collimated SP which illuminates a portion of the interface and induces there local “equivalent SP surface currents” which produce the TD reflected and transmitted fields. Restricting the analysis to the high frequency range, the equivalent surface currents are approximated by their local Physical Optics (PO) values, which renders the reflection and transmission problem equivalent to radiation from a locally varying time-delayed SP aperture field distribution along the interface profile. This SP-PO current distribution is parameterized in terms of Gabor-based narrow-waisted ray-like discretized Gaussian initial fields on the interface which generate reflected/transmitted pulsed beam (PB) propagators. The field at the observer in either half space is established by summation over the SP-PO basis beams.

The problem strategy outlined above implements a further step in our planned sequential approach toward a robust physically incisive, accurate and numerically efficient high frequency asymptotic algorithm that quantifies SP scattering of 3D vector fields by 2D moderately rough interface profiles between different dielectric media (which may be lossy). The intended application is as a rapid forward solver in SP-TD inverse scattering and imaging scenarios where a dielectric rough interface plays a critical role (our approach differs from several numerical/statistical approaches that have been explored in the past (see, e.g., [3]–[5] and the references therein)). The general problem of SP-TD fields excited by 1D planar aperture distributions parameterized in terms of SP Gaussian beams (GB) has already been addressed in one of our previous investigations [2]. The new step in the present problem is the inversion to the SP-TD of the scattered fields in our previous study that deals with the same complete 2D problem geometry but excited by time-harmonic high frequency illumination; here the discretized Gabor basis for the 1D planar truncated aperture distribution involves ray-like frequency domain GB propagators [1]. The coordination of [2] with the SP-TD inversion of the reflected/transmitted fields in [1] occupies the remainder of this paper. After the problem statement in Sec. II, we re-examine in Sec. III the high frequency solution in [1], and modify it by introducing the PO approximation for the induced surface fields on the interface in order to facilitate *explicit* analytic inversion to the SP-TD later on; the corresponding PO-modified asymptotic Gabor beam propagators excited by illumination from a quasi-linearly-phased truncated aperture distribution are developed here. The inversion to the SP-TD is treated in Sec. IV, with preliminary frequency domain approximations for slightly lossy dielectrics as well as certain basis beam parameters that adapt the inversion to the SP-TD aperture field parameterization in [2]. The numerical experiments in Sec. V, performed for a variety of different problem parameters, assess and quantify the accuracy and range of validity of the explicit, compact, physics-based computationally efficient algorithm in Sec. IV through comparison with a rigorously-based numerical reference solution. Conclusions are briefly stated in Sec. VI.

II. STATEMENT OF THE PROBLEM

The problem geometry is sketched in Fig. 1. All fields and geometries are two-dimensional (2D) in the y -independent (x, z) space. A transverse magnetic (TM) po-

larized pulsed electromagnetic (EM) field is assumed to impinge from free space onto a homogeneous lossy dielectric half-space bounded by an irregular interface described by a continuous function $h(x)$ (Fig. 1a).

A. Incident Field

We restrict our attention to the y -directed electric field $e(x, z, t)$ from which all other field quantities of interest can be computed via Maxwell's equations. The y -directed incident field e^i is generated by a large truncated 1D aperture of width d at $z = z_A$, with an assigned space-time electric field distribution $f(x, t)$,

$$e^i(x, z = z_A, t) = \begin{cases} f(x, t), & |x - x_A| \leq d/2, \\ 0, & |x - x_A| > d/2, \end{cases} \quad (1)$$

where x_A is a spatial shift which can be used to adjust the illumination. In what follows, we shall be concerned with pulsed well-collimated Gaussian beams (GBs) generated by the separable linear-delay space-time field distributions

$$f(x, t) = g[(x - x_A) \cos \theta_A] p[t - c^{-1}(x - x_A) \sin \theta_A]. \quad (2)$$

In (2), $g(x)$ is a Gaussian taper function and $c = (\epsilon_0 \mu_0)^{-1/2}$ is the free-space wavespeed, with ϵ_0, μ_0 denoting the free-space permittivity and permeability, respectively. Moreover, $p(t)$ is a short pulse of length $T \ll d/c$, and θ_A denotes the tilt angle of the radiated beam relative to the z -axis (Fig. 1b). The variance of $g(x)$ and the spatial shift x_A are chosen so that $f(x, t)$ tapers to zero for $|x| > d/2$, as shown in Fig. 1b. The linear-delay aperture field distribution in (2) generates a *wide-waisted* tilted GB which, in the collimation zone of the aperture, can be approximated by a pulsed tapered plane wave,

$$e^i(x, z, t) \sim g(x_B) p(t - c^{-1} z_B), \quad (3)$$

where (x_B, z_B) are beam centered coordinates (Fig. 1b)

$$\begin{bmatrix} x_B \\ z_B \end{bmatrix} = \begin{bmatrix} \cos \theta_A & \sin \theta_A \\ \sin \theta_A & -\cos \theta_A \end{bmatrix} \begin{bmatrix} x - x_A \\ z - z_A \end{bmatrix}. \quad (4)$$

The reference solutions employed later on are based on the incident field generated by numerical evaluation of the rigorous Kirchhoff aperture (line source Green's function) integration using (1) and (2) (with (10)), whereas all subsequent beam-derived results rely on the plane wave approximation in (3).

B. Reflected and Transmitted Fields

The irradiated half-space is assumed to be nonmagnetic, i.e., with relative permeability $\mu_r = 1$, and characterized by the constant relative permittivity ϵ_r and electric conductivity σ , both being frequency independent. The interface profile is assumed to be *moderately* rough (both in height and slope) with respect to the pulse length T , i.e., the undulations in $h(x)$ are assumed to be on the order of cT . The reflected and transmitted fields are modeled via the Gabor-based narrow-waisted discretized pulsed beam (PB) algorithm in [2], to which we shall refer frequently throughout the paper. Notationally, we shall use $(\alpha.\beta)$ to denote eq. (β) in ref. $[\alpha]$; for instance, (1.6) means eq. (6) in ref. [1].

III. FREQUENCY DOMAIN FORMULATION

A Gabor-based, narrow-waisted beam approach for time-harmonic scattering by, and transmission through, moderately rough interfaces has been introduced in [1], [6], extending the results in [7], [8], and yielding a robust and efficient numerical algorithm. Although extension of this approach to *pulsed* excitation, via analytic Fourier inversion, is possible in principle, its implementation is indirect and cumbersome. In particular, multiple interactions, which can be treated conveniently in the frequency domain (FD) (see Appendix A in [1]), would involve substantial preliminary algebra in the time domain (TD). Accordingly, we pursue here a simplified approach based on the FD Kirchhoff Physical Optics (PO) approximation which, via the algorithm in [2], can be more easily inverted to the TD. In this section, we briefly review the FD PO formulation and its Gabor-based narrow-waisted beam discretization. Capital letters identify FD field quantities.

A. Physical Optics Approximation

The Kirchhoff PO approximation has been used extensively for scattering from smoothly curved structures which are large on the wavelength scale [9]. Although most

applications have been carried out for impenetrable structures, penetrable objects can be handled as well (see, e.g., [10]). Applications to *conducting* rough surface scattering have also received much attention (see, e.g., [11]–[14]). For *penetrable* rough interfaces, we return to the geometry in Fig. 1a, subject to the pulsed tapered plane-wave illumination in (3), with FD spectrum

$$E^i(x, z, \omega) \sim g(x_B)P(\omega) \exp(ik_0 z_B). \quad (5)$$

Here, (x_B, z_B) are the beam coordinates defined in (4), $k_0 = \omega/c = 2\pi/\lambda_0$ is the free-space wavenumber, λ_0 is the free-space wavelength, and $P(\omega)$ is the spectrum of the pulse $p(t)$,

$$P(\omega) = \int_{-\infty}^{\infty} p(t) \exp(i\omega t) dt. \quad (6)$$

The y -directed FD PO reflected field in the half-space $z > h(x)$ can be expressed as (see, e.g., [15])

$$E^r(x, z, \omega) \sim - \int_{C_{PO}} J_{PO}^r(x', \omega) \frac{\partial}{\partial \zeta} G_{2D}(x, z; x', h(x'); k_0) d\ell', \quad (7)$$

where C_{PO} extends over the illuminated portion of the 1D surface $z = h(x)$, $d\ell'$ is the incremental arc-length measured along the surface tangent,

$$d\ell' = \sqrt{1 + \left(\frac{dh}{dx}(x')\right)^2} dx', \quad \frac{dh}{dx}(x') \equiv \frac{dh}{dx}(x) \Big|_{x'}, \quad (8)$$

and $\partial/\partial\zeta$ denotes the normal derivative (Fig. 2)

$$\frac{\partial}{\partial \zeta} \equiv \left[1 + \left(\frac{dh}{dx}(x')\right)^2 \right]^{-1/2} \left[\frac{\partial}{\partial z} - \frac{dh}{dx}(x') \frac{\partial}{\partial x} \right]. \quad (9)$$

As stated previously, the incident field tapering is chosen so that the illuminated portion of the interface, C_{PO} , is essentially confined to the interval $|x| \leq d/2$ (see Fig. 1b). In (7), G_{2D} is the FD line-source Green's function,

$$G_{2D}(x, z; x', z'; k) = \frac{i}{4} H_0^{(1)}(kR), \quad R = [(x - x')^2 + (z - z')^2]^{1/2}, \quad (10)$$

with $H_0^{(1)}(\cdot)$ denoting the zeroth order Hankel function of the first kind. The induced PO “surface current” density J_{PO}^r is given by twice the tangential reflected field at the interface, obtained from the canonical solution of infinite plane-wave scattering by a plane dielectric boundary locally tangent to the rough surface profile (Fig. 2)

$$J_{PO}^r(x, \omega) = 2\mathcal{R}(x, \omega)E^i(x, h(x), \omega). \quad (11)$$

In (11), \mathcal{R} denotes the local TM plane-wave Fresnel reflection coefficient,

$$\mathcal{R}(x, \omega) = \frac{\cos \theta^i - (\epsilon_r^e - \sin^2 \theta^i)^{1/2}}{\cos \theta^i + (\epsilon_r^e - \sin^2 \theta^i)^{1/2}}, \quad (12)$$

where

$$\epsilon_r^e(\omega) = \epsilon_r + i \frac{\sigma}{\omega \epsilon_0} \quad (13)$$

is the *effective* complex relative permittivity, and θ^i is the local incidence angle relative to the normal, which can be expressed in terms of the incident beam tilt angle θ_A and the local slope α as (see Fig. 2)

$$\theta^i(x) = \theta_A - \alpha(x), \quad \alpha(x) = \tan^{-1} \left[\frac{dh}{dx}(x) \right]. \quad (14)$$

The same considerations applied to the field transmitted into the half-space $z < h(x)$ yield

$$E^t(x, z, \omega) \sim \int_{C_{PO}} J_{PO}^t(x', \omega) \frac{\partial}{\partial \zeta} G_{2D}(x, z; x', h(x'); k) d\ell', \quad (15)$$

where $k = \sqrt{\epsilon_r^e} k_0$ and the PO surface current density J_{PO}^t is given by

$$J_{PO}^t(x, \omega) = 2[1 + \mathcal{R}(x, \omega)]E^i(x, h(x), \omega). \quad (16)$$

The limitations of the Kirchhoff PO approximation have been thoroughly investigated in the past and are well documented in the technical literature (for the case of conducting rough surface scattering see, e.g., [11]). In general, this approximation works well for large, smooth scatterers, and for observation directions not far from backscatter. The

formulations in (7) and (15) neglect multiple interactions, which can be incorporated in principle through higher-order models (see, e.g., [14]). Here, we restrict the range of validity to moderate roughness (both in height and slope) and incidence directions far from grazing, thereby avoiding multiple scattering.

B. Gabor-Based Narrow-Waisted Gaussian Beam Discretization

The FD PO integrals in (7), (15) are formally analogous to the FD Kirchhoff aperture radiation integrals in [2, Sec. II] (see (2.2)). The only difference is that the line integration in (7), (15) is performed along the 1D rough surface profile $z = h(x)$ instead of a 1D planar aperture as in (2.2). In [2], the assigned FD planar aperture field distribution is parameterized in terms of x -domain discretized m -indexed Gabor basis functions with narrow width L , centered on the Gabor lattice points $x_m = mL$ on the aperture; these initial conditions generate *narrow-waisted*, quasi-ray Gaussian beams (GB) which can be approximated efficiently in terms of *complex source point* (CSP) propagators (see (2.14)). *Nontilted* beams, launched from the Gabor lattice points and propagating along the direction *normal* to the aperture plane, are superposed to synthesize the radiated field (see (2.13)), with the Gabor coefficients approximated efficiently by *sampling* the aperture field distribution (see (2.12)). All other *tilted* beams in the full Gabor GB expansion (2.8), which are evanescent for $L \lesssim \lambda_0 \ll d$, are neglected. For linearly phased apertures (cf. (2.17)), a more efficient parameterization is obtained by exploiting propagation-matched tilted beams (cf. (2.18)-(2.22)). For *plane* dielectric interfaces, the plane-wave-excited PO “surface currents” would be *exactly* linearly phased; therefore the tilted beam discretization in (2.18)-(2.22) could be applied straightforwardly and, as shown in [2, Sec. II-C], would be considerably more efficient than the nontilted algorithm in (2.13)-(2.16). For *moderately rough* interfaces, the phasing in the PO surface currents is no longer *globally* linear. However, for narrow-waisted beams, one can still exploit the *locally* linear behavior. To this end, it is expedient to rewrite the PO currents by separating out the locally linear phase term that the incident plane wave would induce on the locally tangent plane, i.e., (generalizing (2.17))

$$J_{PO}^\nu(x) = \mathcal{J}_{PO}^\nu(x) \exp[ik_0 x \sin \theta^i(x) \cos \alpha(x)], \quad \nu = r \text{ or } t, \quad (17)$$

with $\theta^i(x)$ defined in (14). Here and henceforth the ω dependence is omitted for simplicity of notation. The weakly phased *reduced* PO currents

$$\mathcal{J}_{PO}^\nu(x) = J_{PO}^\nu(x) \exp[-ik_0 x \sin \theta^i(x) \cos \alpha(x)], \quad \nu = r \text{ or } t \quad (18)$$

can thus be parameterized approximately as (see (2.18)-(2.19))

$$\mathcal{J}_{PO}^\nu(x) \approx \sum_{|m| \leq (d/2L)} C_m^\nu w(x - x_m), \quad \nu = r \text{ or } t, \quad (19)$$

where the subscript m tags the m -th GB in the discretization and $w(\cdot)$ represents the normalized Gaussian window in (2.6),

$$w(x) = \left(\frac{\sqrt{2}}{L} \right)^{1/2} \exp \left[-\pi (x/L)^2 \right], \quad \int_{-\infty}^{\infty} w^2(x) dx = 1, \quad (20)$$

with the Gabor coefficients C_m^ν given approximately by

$$C_m^\nu = \left(\frac{L}{\sqrt{2}} \right)^{1/2} \mathcal{J}_{PO}^\nu(x_m), \quad \nu = r \text{ or } t. \quad (21)$$

The sum in (19) extends up to $|m| \leq d/2L$ because the PO surface currents (subject to verification) are assumed to be negligible for $|x| \geq d/2$, outside the illumination window (see Fig. 1b). By combining (7) and (15) with (17) and (19), the reflected and transmitted fields can be discretized as (see also (2.18))

$$E^\nu(x, z) \sim \frac{1}{2} \sum_{|m| \leq (d/2L)} C_m^\nu \mathcal{B}_m^\nu(x, z), \quad \nu = r \text{ or } t, \quad (22)$$

where the beam propagators $\mathcal{B}_m^r, \mathcal{B}_m^t$ are given by

$$\mathcal{B}_m^r(x, z) = -2 \int_{C_{PO}} w(x' - x_m) \frac{\partial}{\partial \zeta} G_{2D}(x, z; x', h(x'); k_0) \exp[ik_0 x' \sin \theta^i(x') \cos \alpha(x')] d\ell', \quad (23)$$

$$\mathcal{B}_m^t(x, z) = 2 \int_{C_{PO}} w(x' - x_m) \frac{\partial}{\partial \zeta} G_{2D}(x, z; x', h(x'); k) \exp[ik_0 x' \sin \theta^i(x') \cos \alpha(x')] d\ell'. \quad (24)$$

For narrow Gaussian windows, i.e., $L \lesssim \lambda_0 \ll d$, and moderate surface roughness, the paraxial far zone approximation in [7] can be applied to (23) and (24). For the reflected field, one obtains the following *complex source point* (CSP) approximation which applies (2.20) locally (see Appendix A for details)

$$\begin{aligned} \mathcal{B}_m^r(x, z) \sim & -ik_0 2^{5/4} \left(\frac{L}{8\pi k_0} \right)^{1/2} \frac{(\zeta_m - ib_m^r \cos \theta_m^i)}{(\tilde{R}_m^r)^{3/2}} \\ & \cdot \exp \left\{ i \left[k_0 \left(\tilde{R}_m^r + x_m \sin \theta_m^i \cos \alpha_m + ib_m^r \right) + \pi/4 \right] \right\}, \end{aligned} \quad (25)$$

where (see Fig. 3) $\theta_m^i \equiv \theta^i(x_m)$, $\alpha_m \equiv \alpha(x_m)$,

$$\zeta_m = -(x - x_m) \sin \alpha_m + [z - h(x_m)] \cos \alpha_m. \quad (26)$$

Furthermore,

$$\tilde{R}_m^r = \sqrt{(x_{bm}^r)^2 + (z_{bm}^r - ib_m^r)^2}, \quad \text{Re}[\tilde{R}_m^r] \geq 0, \quad (27)$$

is the complex distance, in the beam coordinates of Fig. 3, between the observation point

$$\begin{bmatrix} x_{bm}^r \\ z_{bm}^r \end{bmatrix} = \begin{bmatrix} \cos \gamma_m^r & -\sin \gamma_m^r \\ \sin \gamma_m^r & \cos \gamma_m^r \end{bmatrix} \begin{bmatrix} x - x_m \\ z - h(x_m) \end{bmatrix}, \quad \gamma_m^r = \theta_m^i - \alpha_m = \theta_A - 2\alpha_m, \quad (28)$$

and the CSP $(0, ib_m^r)$, with the complex displacement parameter b_m^r given by (generalizing (2.22)),

$$b_m^r = (L \cos \alpha_m \cos \theta_m^i)^2 / \lambda_0. \quad (29)$$

Here and henceforth, the tilde \sim identifies dependence on analytically continued spatial source coordinates. The beam discretization in (22) with the CSP propagators in (25) is physically appealing because it represents a superposition of GBs launched from points $(x_m, h(x_m))$ on the illuminated portion of the interface along the reflection directions γ_m^r (see Fig. 3), which are *locally matched* to the surface currents. Similarly, for the transmitted field one obtains

$$\mathcal{B}_m^t(x, z) \sim ik 2^{5/4} \left(\frac{L}{8\pi k} \right)^{1/2} \frac{(\zeta_m - ib_m^t \cos \theta_m^R)}{(\tilde{R}_m^t)^{3/2}}.$$

$$\cdot \exp \left\{ i \left[k \left(\tilde{R}_m^t + x_m \sin \theta_m^R \cos \alpha_m + i b_m^t \right) + \pi/4 \right] \right\}, \quad (30)$$

where θ_m^R is the local refraction angle (see Fig. 4), related to θ_m^i and ϵ_r^e via Snell's law

$$\sin \theta_m^i = \sqrt{\epsilon_r^e} \sin \theta_m^R. \quad (31)$$

Moreover, in the beam coordinates of Fig. 4, \tilde{R}_m^t is the complex distance

$$\tilde{R}_m^t = \sqrt{(x_{bm}^t)^2 + (z_{bm}^t - i b_m^t)^2}, \quad \text{Re}[\tilde{R}_m^t] \geq 0, \quad (32)$$

with

$$\begin{bmatrix} x_{bm}^t \\ z_{bm}^t \end{bmatrix} = \begin{bmatrix} \cos \gamma_m^t & \sin \gamma_m^t \\ \sin \gamma_m^t & -\cos \gamma_m^t \end{bmatrix} \begin{bmatrix} x - x_m \\ z - h(x_m) \end{bmatrix}, \quad \gamma_m^t = \theta_m^R + \alpha_m, \quad (33)$$

and the complex displacement parameter given by

$$b_m^t = \sqrt{\epsilon_r^e} (L \cos \alpha_m \cos \theta_m^R)^2 / \lambda_0. \quad (34)$$

Like the reflected field, the transmitted field is synthesized via (22) and (30) with *surface current-matched* CSP GBs propagating along the *local refraction direction* γ_m^t (see Fig. 4). Since the dielectric half-space is assumed to be lossy, θ_m^R , γ_m^t and b_m^t are complex.

IV. TIME DOMAIN FORMULATION

A. Preliminary Considerations

The FD beam propagators in (25) and (30) are nearly identical with that in (2.20). Therefore, extension to the time domain (TD) for pulsed excitation can be pursued by following the procedure in [2, Sec. III-A]. However, the TD inversion is now complicated by the dispersive (Ohmic) properties of the dielectric half-space (cf. (13)). Although analytic approaches to PB propagation in Ohmic-dispersive media are available [16], here we use a simpler approach, restricted to slightly lossy materials, i.e.,

$$\frac{\sigma}{\omega \epsilon_0 \epsilon_r} \ll 1, \quad \omega < \Omega, \quad (35)$$

with Ω denoting the effective bandwidth of the pulse $p(t)$. This condition is fulfilled for a class of actual ground penetrating radar (GPR) applications which is of interest to us

(see, e.g., the discussion in [17]), and which allows the complex wavenumber to be written as [17]

$$k = \frac{\omega}{c} \sqrt{\epsilon_r^e} \approx \sqrt{\epsilon_r} \frac{\omega}{c} \left(1 + i \frac{\sigma}{2\omega\epsilon_0\epsilon_r} \right) = \sqrt{\epsilon_r} \frac{\omega}{c} + i \frac{\sigma}{2c\epsilon_0\sqrt{\epsilon_r}}, \quad (36)$$

i.e., with a *frequency-independent* imaginary part. This *nondispersive* approximation considerably simplifies the TD inversion. In what follows, we shall be using (36) for calculating the transmitted field. Moreover, we approximate the frequency-dependent reflection coefficient in (12) by its value at the center angular frequency Ω_0 of the pulse,

$$\mathcal{R}(x, \omega) \approx \mathcal{R}_0(x) \equiv \mathcal{R}(x, \Omega_0). \quad (37)$$

As in [2], we assume a frequency-independent Gabor lattice parameter L in order to conveniently estimate the TD Gabor coefficients by aperture sampling (see the discussion in [2, Sec. III-A]). Anticipating Fourier inversion, recalling (5), (11), (16), (18) and (37), the FD Gabor coefficients in (21) can be written as

$$C_m^\nu \approx 2c_m^\nu P(\omega) \exp(i\omega t_m), \quad \nu = r \text{ or } t, \quad (38)$$

where

$$c_m^r = (L/\sqrt{2})^{1/2} g(x_{Bm}) \mathcal{R}_0(x_m), \quad c_m^t = (L/\sqrt{2})^{1/2} g(x_{Bm}) [1 + \mathcal{R}_0(x_m)] \quad (39)$$

are frequency independent, and

$$t_m = c^{-1} \left(z_{Bm} - x_m \sin \theta_m^i \cos \alpha_m \right), \quad (40)$$

with (x_{Bm}, z_{Bm}) denoting the lattice points $(x_m, h(x_m))$ in the incident-beam coordinates (4),

$$\begin{bmatrix} x_{Bm} \\ z_{Bm} \end{bmatrix} = \begin{bmatrix} \cos \theta_A & \sin \theta_A \\ \sin \theta_A & -\cos \theta_A \end{bmatrix} \begin{bmatrix} x_m - x_A \\ h(x_m) - z_A \end{bmatrix}. \quad (41)$$

The FD Gabor expansions in (22) can thus be rewritten as

$$E^\nu(x, z, \omega) \sim \sum_{|m| \leq (d/2L)} c_m^\nu P(\omega) \mathcal{B}_m^\nu(x, z, \omega) \exp(i\omega t_m), \quad \nu = r \text{ or } t. \quad (42)$$

As in [2], in order to deal with the evanescent spectra in the beam propagators \mathcal{B}_m^r and \mathcal{B}_m^t , the TD is accessed by Fourier inversion of (42) via the analytic signal formulation (cf. (2.31), (2.32)) [18]

$$f^+(t) = \frac{1}{\pi} \int_0^\infty F(\omega) \exp(-i\omega t) d\omega, \quad \text{Im}(t) \leq 0, \quad (43)$$

where $F(\omega)$ is the conventional Fourier spectrum of the real signal $f(t)$, and the real signal for real t is recovered via

$$f(t) = \text{Re} \left[f^+(t) \right]. \quad (44)$$

Accordingly (cf. (2.33)),

$$e^\nu(x, z, t) \sim \sum_{|m| \leq (d/2L)} c_m^\nu \mathbf{b}_m^\nu(x, z, t - t_m), \quad \nu = r \text{ or } t, \quad (45)$$

with the analytic PB propagators \mathbf{b}_m^ν given by

$$\mathbf{b}_m^\nu(x, z, t) = \frac{1}{\pi} \int_0^\infty \mathcal{B}_m^\nu(x, z, \omega) P(\omega) \exp(-i\omega t) d\omega, \quad \text{Im}(t) \leq 0, \quad \nu = r \text{ or } t, \quad (46)$$

and the real TD fields obtained from

$$e^\nu(x, z, t) = \text{Re} \left[\mathbf{e}^\nu(x, z, t) \right], \quad \nu = r \text{ or } t. \quad (47)$$

The analytic PB propagators \mathbf{b}_m^r and \mathbf{b}_m^t in (46) should not be confused with the complex displacement parameters b_m^r and b_m^t in (29) and (34), respectively.

As in [2], we consider a class of Rayleigh (differentiated Gaussian) pulses (cf. (2.37), (2.38)),

$$p(t) = \Xi \frac{d^j}{dt^j} \exp \left[- \left(\frac{t - T/2}{\varsigma T} \right)^2 \right], \quad (48)$$

$$P(\omega) = \sqrt{\pi} \Xi \varsigma T (-i\omega)^j \exp \left(-\frac{\varsigma^2 \omega^2 T^2}{4} + i \frac{\omega T}{2} \right), \quad (49)$$

where Ξ is a normalization constant, and the variance ς is chosen so that the pulse width of $p(t)$ is $\sim T$. We now generalize the TD results in [2, Sec. III-A], starting with the reflected field.

B. Reflected Field

As in [2], in order to evaluate the integral in (46) with (25) and (49), we first approximate the complex distance \tilde{R}_m^r in (27), which is frequency dependent via (29). Assuming L/λ_0 (and therefore b_m^r) sufficiently small in the amplitude factor of (25) we let (cf. (2.39))

$$\frac{(\zeta_m - ib_m^r \cos \theta_m^i)}{(\tilde{R}_m^r)^{3/2}} \approx \frac{\zeta_m}{(R_m^r)^{3/2}}, \quad R_m^r = \sqrt{(x_{bm}^r)^2 + (z_{bm}^r)^2}, \quad b_m^r \ll \zeta_m, z_{bm}^r, \quad (50)$$

where R_m^r is real and frequency-independent, with ζ_m and (x_{bm}^r, z_{bm}^r) defined in (26) and (28), respectively. In the phase factor, instead of the paraxial approximation in (2.40), we use a perturbation (first-order McLaurin) approximation in terms of b_m^r (see (29)),

$$\tilde{R}_m^r(\omega) \approx R_m^r - ib_m^r \frac{z_{bm}^r}{R_m^r} = R_m^r - i\omega \frac{z_{bm}^r (L \cos \alpha_m \cos \theta_m^i)^2}{2\pi c R_m^r}, \quad b_m^r \ll z_{bm}^r, \quad (51)$$

which was found to give better results. Using (50) and (51), the beam propagator in (25) can be rewritten as

$$\mathcal{B}_m^r(x, z, \omega) \sim \Lambda_m^r \omega^{1/2} \exp[-(\omega T_m^r)^2/4 + i\omega \tau_m^r], \quad (52)$$

where

$$\Lambda_m^r = -i2^{5/4} \exp(i\pi/4) c^{-1} \sqrt{\frac{L}{8\pi}} \frac{\zeta_m}{(R_m^r)^{3/2}}, \quad (53)$$

$$\tau_m^r = c^{-1} (R_m^r + x_m \sin \theta_m^i \cos \alpha_m + T/2), \quad T_m^r = \frac{L \cos \alpha_m \cos \theta_m^i}{2c\sqrt{2\pi}} \sqrt{1 - \frac{z_{bm}^r}{R_m^r}}. \quad (54)$$

Substituting (49) and (52) into (46), one obtains a canonical integral [19],

$$\begin{aligned}
I(p, q, j) &= \int_0^\infty \omega^{j+1/2} \exp(ip\omega - q^2\omega^2/4) d\omega = \\
&= 2^{j+1/2} q^{-j-5/2} \left[q \Gamma\left(\frac{3+2j}{4}\right) M_1^{(j)}\left(\frac{p}{q}\right) + 2ip \Gamma\left(\frac{5+2j}{4}\right) M_2^{(j)}\left(\frac{p}{q}\right) \right], \quad q \in R^+, \quad (55)
\end{aligned}$$

where $\Gamma(\cdot)$ is the gamma function [20], and

$$M_1^{(j)}(t) = {}_1F_1\left(\frac{3+2j}{4}, \frac{1}{2}, -t^2\right), \quad M_2^{(j)}(t) = {}_1F_1\left(\frac{5+2j}{4}, \frac{3}{2}, -t^2\right), \quad (56)$$

with ${}_1F_1(u, v, t)$ denoting the Kummer confluent hypergeometric function [20]. The reflected analytic PB propagator can be thus written as

$$b_m^+(x, z, t) = (-1)^j \beta_m^r \left[\mathcal{T}_m^r \Gamma\left(\frac{3+2j}{4}\right) M_1^{(j)}\left(\frac{t - \tau_m^r}{\mathcal{T}_m^r}\right) - 2i(t - \tau_m^r) \Gamma\left(\frac{5+2j}{4}\right) M_2^{(j)}\left(\frac{t - \tau_m^r}{\mathcal{T}_m^r}\right) \right], \quad (57)$$

where

$$\beta_m^r = 2^{j+1/2} \pi^{-1/2} (\mathcal{T}_m^r)^{-j-5/2} \Lambda_m^r \Xi \zeta T, \quad \mathcal{T}_m^r = \sqrt{(T_m^r)^2 + \zeta^2 T^2}. \quad (58)$$

Equation (57) generalizes (2.44) to arbitrary order j of the derivative in (48). The functions $M_{1,2}^{(j)}$ can be efficiently computed using the rapidly converging expansions in Appendix B.

C. Transmitted Field

The transmitted PB propagator can be obtained similarly. The only slight difference is due to the complex wavenumber k and the complex parameters θ_m^R and b_m^t in (30) (see (31) and (34)). For slightly lossy materials as in (35), the complex wavenumber is approximated via (36), whereas θ_m^R and b_m^t are approximated by the real values

$$\theta_m^R \approx \theta_{m0}^R \equiv \sin^{-1} \left(\sin \theta_m^i / \sqrt{\epsilon_r} \right), \quad b_m^t \approx b_{m0}^t \equiv \sqrt{\epsilon_r} (L \cos \alpha_m \cos \theta_{m0}^R)^2 / \lambda_0. \quad (59)$$

Accordingly,

$$b_m^+(x, z, t) = (-1)^j \beta_m^t \left[\mathcal{T}_m^t \Gamma\left(\frac{3+2j}{4}\right) M_1^{(j)}\left(\frac{t - \tau_m^t}{\mathcal{T}_m^t}\right) - 2i(t - \tau_m^t) \Gamma\left(\frac{5+2j}{4}\right) M_2^{(j)}\left(\frac{t - \tau_m^t}{\mathcal{T}_m^t}\right) \right], \quad (60)$$

where

$$\beta_m^t = 2^{j+1/2} \pi^{-1/2} (\mathcal{T}_m^t)^{-j-5/2} \Lambda_m^t \Xi \zeta T, \quad \mathcal{T}_m^t = \sqrt{(T_m^t)^2 + \zeta^2 T^2}, \quad (61)$$

$$\Lambda_m^t = i(\epsilon_r)^{1/4} 2^{5/4} \exp(-\kappa R_{m0}^t + i\pi/4) c^{-1} \sqrt{\frac{L}{8\pi}} \frac{\zeta_m}{(R_{m0}^t)^{3/2}}, \quad \kappa = \frac{\sigma}{2c\epsilon_0 \sqrt{\epsilon_r}}, \quad (62)$$

$$\tau_m^t = c^{-1} \left[\sqrt{\epsilon_r} (R_{m0}^t + x_m \sin \theta_{m0}^R \cos \alpha_m) + T/2 \right], \quad T_m^t = \sqrt{\epsilon_r} \frac{L \cos \alpha_m \cos \theta_{m0}^R}{2c\sqrt{2\pi}} \sqrt{1 - \frac{z_{bm0}^t}{R_{m0}^t}}, \quad (63)$$

$$R_{m0}^t = \sqrt{(x_{m0}^t)^2 + (z_{m0}^t)^2}, \quad \begin{bmatrix} x_{bm0}^t \\ z_{bm0}^t \end{bmatrix} = \begin{bmatrix} \cos \gamma_{m0}^t & \sin \gamma_{m0}^t \\ \sin \gamma_{m0}^t & -\cos \gamma_{m0}^t \end{bmatrix} \begin{bmatrix} x - x_m \\ z - h(x_m) \end{bmatrix}, \quad \gamma_{m0}^t = \theta_{m0}^R + \alpha_m, \quad (64)$$

D. Limitations

The limitations of the proposed approach can be divided into two categories. The first category includes the *model constraints*, i.e., the underlying PO approximation and all other simplifying assumptions. These constraints are known *a priori*, and can be summarized as follows

- i) Moderately rough interfaces (both in height and slope) with local curvature radii large compared to the pulse length cT ;
- ii) Plane-wave excitation (cf. (3)) with incidence direction far from grazing;
- iii) Slightly lossy dielectrics (cf. (35)).

Strong roughness and/or near-grazing incidence would require more sophisticated models than the simple PO approximation in Sec. III-A. More general (e.g., focused) excitations would require a two-step procedure: first discretizing the aperture field distribution in terms of narrow-waisted GBs as in [2] and subsequently applying the PO algorithm to each incident beam. More sophisticated loss/dispersion models could also be included in principle [16].

The second type of constraint is related to the adequacy of the narrow-waisted PB discretization in Secs. IV-B and IV-C, in terms of the number of beams required to guar-

antee stability of the outcome. We have referred to this as the *scrambling* criterion, i.e., the insensitivity of the result with respect to different combinations of the beam/lattice configuration. Overall reliability requires that both the model constraints and the scrambling criterion are satisfied.

V. NUMERICAL RESULTS

A. Reference Solution

The PB syntheses presented in Sec. IV have been validated and calibrated against an independent reference solution based on the time-harmonic multifilament current method in [21], adapted to moderately rough interfaces (cf. App. B in [1]). The frequency spectra of the reflected and transmitted fields were obtained by solving the FD problem at 100 different frequencies within the pulse bandwidth. The incident FD field was computed via numerical integration of the rigorous Kirchhoff aperture distribution (the spectrum of (2)), without resorting to the plane wave approximation, and with use of the full dispersive permittivity model in (13) for the dielectric half-space. The resulting frequency samples were smoothed through local Padé-approximation [22] and filtered by the pulse spectrum $P(\omega)$ in (49). The TD solution was then obtained via standard inverse FFT routines [22].

B. Simulation Parameters

The numerical simulations that follow are based on the pulsed aperture field distribution in (2) with the Gaussian taper

$$g(x) = \exp[-18x^2/(d \cos \theta_A)^2], \quad (65)$$

and the wideband fourth-order Rayleigh pulse $p(t)$, obtained from (48) with $j = 4$, $\Xi = T^4/30000$, $\varsigma = 1/\sqrt{50}$, and length $cT = 0.08d$ (see Fig. 5a), which has a center angular frequency $\Omega_0 = 20/T$ (see Fig. 5b). For the reflected/transmitted fields, the special functions $M_{1,2}^{(4)}$ in (57) and (60) were computed via the rapidly converging expansions in Appendix B with $N = 5$ (cf. (2.50) and (2.51)). The aperture height z_A was chosen so as to place the rough dielectric interface within the collimation zone of the aperture, thereby justifying the plane-wave incidence approximation in (3); depending on the tilt

angle θ_A , the spatial shift x_A was adjusted so that the illuminated region was confined in the interval $[-d/2, d/2]$ (see Fig. 1b). In each of the examples below, it was verified that the illumination at the edges $x = \pm d/2$ was at least 30 dB below the maximum strength so that numerical artifacts due to edge effects were negligible. The rough surface profile was generated via the quartic spline model in [1]. For the GPR applications of interest in our studies, the dielectric half-space parameters were chosen so as to simulate a class of realistic soils (Puerto Rican clay loam [23]), with the frequency range chosen to satisfy (35).

C. Results

We begin with the problem geometry in Fig. 6, with the relevant parameters specified in the figure caption. For this configuration, the roughness is moderate both in height ($h_{max} = 0.36cT$) and slope ($\phi_{max} = 31^\circ$), and the average radius of curvature \bar{r}_c is large with respect to the pulse length ($\bar{r}_c = 5.9cT$). The incident field direction is vertical ($\theta_A = 0$), and the constitutive parameters ϵ_r, σ satisfy (35). The previously stated conditions for validity of the proposed PB synthesis in (47) should be thus satisfied, and good accuracy should be expected with an “adequate” number of beams. The reflected and transmitted fields have been computed via (47) with (57) and (60), respectively, at nine observation points (three different horizontal positions, spanning the illuminated region, on three observation planes). The reflected/transmitted temporal waveforms obtained via the PB synthesis with 150 beams are shown in Figs. 7 and 8, respectively, and are compared with the reference solution. Very good agreement is observed. The reflected waveforms reveal details which can be tied to the space-time dependent scattering processes. At certain observation points, especially at smaller observation distance (cf. Figs. 7a, 7c, 7f), the dominant contributions turn out to be well separated and replicate the incident waveform (inverted due to reflection). This is not the case in the central region ($x = 0$), where the almost simultaneous arrivals from the surface do not allow their separate resolution for the specified input pulse width, thereby resulting in the chirped oscillations in Figs. 7b, 7e, 7h. Separate (non-inverted) arrivals are also visible in the transmitted field (cf. Fig. 8i); at smaller observation distance (e.g., Figs. 8a, 8c), however, the transmitted field waveforms coalesce into a close replication of the incident pulse. In all examples, the PB

syntheses capture even the finer details.

The number of beams in these examples was arrived at using the pragmatic stability criterion discussed in Sec. IV-D. In order to better quantify the accuracy, and address convergence issues, we have computed the r.m.s. (energy) errors

$$\Delta e^\nu = \frac{\int_{-\infty}^{\infty} |e_r^\nu(x, z, t) - e_b^\nu(x, z, t)|^2 dt}{\left[\int_{-\infty}^{\infty} |e_r^\nu(x, z, t)(x, z, t)|^2 dt \int_{-\infty}^{\infty} |e_b^\nu(x, z, t)(x, z, t)|^2 dt \right]^{1/2}}, \quad \nu = r \text{ or } t, \quad (66)$$

where the subscript $_r$ denotes the reference solution and $_b$ denotes the PB synthesis. The r.m.s. errors for Figs. 7 and 8 are < -25 dB. The convergence of the algorithm in Figs. 7 and 8 is illustrated in Fig. 9, where the r.m.s. errors for both reflected and transmitted fields are plotted vs. the number of beams $N_b = d/L$. The various curves pertain to different observation points. It is noted that beyond a critical threshold, the error becomes *practically insensitive* to a further increase in the number of beams, indicating that convergence has been achieved. “Convergence” here implies that the *PO integral* is adequately beam-discretized but, as noted in Sec. IV-D, this *does not* necessarily imply that the *overall* solution is accurate; good *overall* accuracy requires that the model constraints are likewise satisfied. The test configuration was chosen deliberately so that this is the case. In this example, the convergence turns out to be weakly dependent on the observation point, and a robust threshold for *uniformly* good accuracy ($\Delta e^{r,t} < -25$ dB) can be set around $N_b = 150$. If the *model constraints* in Sec. IV-D were violated, the PB synthesis, although stabilized, could be *inaccurate*. For illustration, we strained the algorithm by selecting simulation parameters near the limit of their range of validity. The results in Fig. 10 pertain to the profile in Fig. 6, conformally scaled so as to increase the roughness up to a maximum height $h_{max} = 0.6cT$ and a maximum slope $\phi_{max} = 46^\circ$, with an average curvature radius $\bar{r}_c = 4.4cT$. The number of beams was chosen to satisfy the stability criterion. Remarkably, the PB synthesis still performs well, but now one observes discrepancies with respect to the reference solution (particularly in one late-time peak (Fig. 10a)) which *cannot* be repaired by increasing the number of beams. Note that the increased roughness admits multiple reflections which are accounted for in the reference solution but

ignored in the PO algorithm. This may contribute to the diminished accuracy, which now yields r.m.s. errors $\Delta e^r = -10$ dB, $\Delta e^t = -20$ dB. The deterioration is aggravated further for oblique incidence, where multiple interactions are more pronounced, as seen in Fig. 11, where the profile of Fig. 10 is illuminated by a tilted beam with $\theta_A = 40^\circ$. For this example, $\Delta e^r = -8$ dB and $\Delta e^t = -9$ dB. We also investigated the accuracy degradation in the “low frequency” (i.e., long pulse) limit. As an illustration, the reflected and transmitted waveforms at various observation points in Fig. 12 pertain to the geometry in Fig. 6, but using a ten-times longer excitation pulse ($cT = 0.8$). For this configuration, $cT = 0.8d$ and $\bar{r}_c = 0.44cT$; the reduced radius of curvature stretches the validity of the asymptotics in the PO model and in the CSP approximations (25) and (30). First, one notes from Fig. 12 that the reflected/transmitted waveforms contain less structure than those in Figs. 7, 8, 10, 11, since the surface is now *flatter* on the pulse length scale ($h_{max} = 0.06cT$). Second, due to the lower-frequency content of the pulse, recalling (29) and (51), a larger Gabor lattice period L (i.e., fewer beams) should be adequate to stabilize the beam synthesis. This was confirmed in numerical simulations, where the beam syntheses were found to stabilize around $N_b = 30$. As seen from Fig. 12, the beam syntheses, though reasonably good, are no longer *highly* accurate, but have r.m.s. errors ranging from -25 dB to -5 dB. As in Figs. 10 and 11, the accuracy *cannot* be improved by increasing the number of beams, indicating that the limit in range of validity of the PO/CSP asymptotics has been reached.

From a practical viewpoint, we have found fairly accurate predictions ($\Delta e^{r,t} \lesssim -20$ dB) for roughness with maximum height $h_{max} \lesssim 0.5cT$, (average) curvature radii $\bar{r}_c \gtrsim 2cT$, maximum slopes $\phi_{max} \lesssim 40^\circ$, for nearly-vertical incidence ($\theta_A \lesssim 30^\circ$), and for dielectrics with $\sigma/(\Omega_0\epsilon_0\epsilon_r) \lesssim 0.05$. For the examples in Figs. 7, 8, 10 and 11, 150–200 beams were usually found to be sufficient to reach convergence, resulting in an average computing time $T_c = 8$ ms per field time-sample (at a fixed observation point) on a 500 MHz PC. Note that the computing time scales linearly with the number of beams; accordingly, for the examples in Fig. 12 (i.e., 30 beams) we found $T_c = 2$ ms.

VI. CONCLUSIONS

A Gabor-based, quasi-ray, pulsed beam (PB) algorithm has been presented for short-pulse 2D reflection by, and transmission through, a 1D moderately rough interface separating free space from a slightly lossy dielectric half-space. The approach is based on the Kirchhoff PO approximation and the PB 1D aperture field discretization in [2], and has been validated and calibrated against an independently generated reference solution. Numerical simulations show that the proposed algorithm yields fast, robust and accurate predictions in a calibrated range of parameters, and therefore is promising as a useful forward model for inverse scattering scenarios that involve buried objects. Extension to more general dispersion/loss models and to non-collimated aperture excitations remain to be investigated. Extension to 2D surfaces, and 3D field scattering, based on 2D aperture PB discretization [24], is straightforward in principle, but its computational features remain to be explored.

APPENDIX A

DETAILS PERTAINING TO EQ. (25)

For narrow Gaussian windows, with $L \lesssim \lambda_0 \ll d$, the integrand in (23) is strongly localized around $x = x_m$. Thus, for moderate roughness, the integration path near x_m can be approximated by the local tangent plane, and the phase function can be assumed to be linear. Accordingly, in the (ξ_m, ζ_m) coordinate system of Fig. 3,

$$\begin{bmatrix} \xi_m \\ \zeta_m \end{bmatrix} = \begin{bmatrix} \cos \alpha_m & \sin \alpha_m \\ -\sin \alpha_m & \cos \alpha_m \end{bmatrix} \begin{bmatrix} x - x_m \\ z - h(x_m) \end{bmatrix}, \quad \alpha_m \equiv \alpha(x_m), \quad (67)$$

the reflected-beam integral in (23) can be approximated as

$$\mathcal{B}_m^r(x, z) \approx -2 \int_{-\infty}^{\infty} w_{\alpha m}(\xi'_m) \frac{\partial}{\partial \zeta_m} G_{2D}(\xi_m, \zeta_m; \xi'_m, 0; k_0) \exp[ik_0(\xi'_m + x_m \cos \alpha_m) \sin \theta_m^i] d\xi'_m, \quad (68)$$

where $w_{\alpha m}(\cdot)$ is the Gaussian window in (20) projected onto the local tangent plane (ξ_m axis in Fig. 3),

$$w_{\alpha m}(x) = w(x/\cos \alpha_m) = \left(\frac{\sqrt{2}}{L}\right)^{1/2} \exp \left[-\pi \left(\frac{x}{L \cos \alpha_m} \right)^2 \right]. \quad (69)$$

The integral in (68) has the same form as (2.9). Therefore, straightforward application of the paraxial far zone approximation detailed in the Appendix of [7] yields the result in (25). Similar considerations applied to the transmitted beams in (24) yield (30) (see Fig. 4).

APPENDIX B

RAPIDLY CONVERGING EXPANSIONS FOR $M_{1,2}^{(j)}$

As in [2, App. C], using the Kummer transformation and the truncated Taylor series for the confluent hypergeometric function ${}_1F_1$, one obtains [20]

$$M_1^{(j)}(t) = \exp(-t^2) {}_1F_1 \left(-\frac{5+j}{4}, \frac{1}{2}, t^2 \right) \approx \exp(-t^2) \sum_{n=0}^N \frac{\left(-\frac{5+j}{4} \right)_n}{\left(\frac{1}{2} \right)_n n!} t^{2n}, \quad (70)$$

$$M_2^{(j)}(t) = \exp(-t^2) {}_1F_1 \left(-\frac{3+j}{4}, \frac{3}{2}, t^2 \right) \approx \exp(-t^2) \sum_{n=0}^N \frac{\left(-\frac{3+j}{4} \right)_n}{\left(\frac{3}{2} \right)_n n!} t^{2n}, \quad (71)$$

with $(u)_n$ denoting the Pochhammer symbol [20],

$$(u)_n = u(u+1)(u+2) \cdots (u+n-1), \quad (u)_0 = 1. \quad (72)$$

As shown in [2, Fig. 5], the expansions in (70) and (71) guarantee satisfactory accuracy with few terms ($N \approx 5$).

Quasi-Ray Gaussian Beam Algorithm for Time-Harmonic Two-Dimensional Scattering by Moderately Rough Interfaces

Vincenzo Galdi, *Member, IEEE*, Leopold B. Felsen, *Life Fellow, IEEE*, and David A. Castañon, *Senior Member, IEEE*

Abstract—Gabor-based Gaussian beam (GB) algorithms, in conjunction with the complex source point (CSP) method for generating beam-like wave objects, have found application in a variety of high-frequency wave propagation and diffraction scenarios. Of special interest for efficient numerical implementation is the noncollimated narrow-waisted species of GB, which reduces the computationally intensive complex ray tracing for collimated GB propagation and scattering to quasi-real ray tracing, without the failure of strictly real ray field algorithms in caustic and other transition regions. The Gabor-based narrow-waisted CSP-GB method has been applied previously [1]–[3] to two-dimensional (2-D) propagation from extended nonfocused and focused aperture distributions through arbitrarily curved 2-D layered environments. In this 2-D study, the method is applied to aperture-excited field scattering from, and transmission through, a moderately rough interface between two dielectric media. It is shown that the algorithm produces accurate and computationally efficient solutions for this complex propagation environment, over a range of calibrated combinations of the problem parameters. One of the potential uses of the algorithm is as an efficient forward solver for inverse problems concerned with profile and object reconstruction [4].

Index Terms—Gabor lattice representations, Gaussian beams, rough surface scattering.

I. INTRODUCTION

REFLECTION from, and transmission through, a rough (irregular) boundary separating two different material media is of interest in many applications. One such application is the detection and classification of buried objects using ground-penetrating radar. This application involves above-ground transmitters and receivers. The twice-traversed air–ground interface is a principal corruptor of the signal on its way to and from the

Fig. 1. Problem geometry. An incident field from an extended tapered aperture field distribution at $z = z_A$ is assumed to impinge on a moderately rough interface, described by the continuous function $h(x)$, separating free space and a dielectric half-space. Reflected and transmitted fields are observed at $z = z_{or}$ and $z = z_{ot}$, respectively.

targets of interest. To enhance the detection and classification processing, it is important to model the distortion introduced by the air–ground interface.

As a first step toward this goal, we investigate in this paper the reflection from, and transmission through, a moderately rough (coarse-scale) interface between air and a homogeneous dielectric (soil) half-space (see Fig. 1); this forward problem constitutes an electromagnetic (EM) scattering problem, and inclusion of the transmitted field anticipates the subsequent interest in computing the scattering from buried objects. In a following paper [4], we shall be concerned with the reconstruction (inverse problem) of the interface profile under the realistic constraints of spatially sampled data. A key ingredient in the reconstruction problem is a fast forward model that can relate descriptions of potential interface profiles to the measured signals at the different receiver locations.

The analytic and numerical modeling of wave scattering from rough surfaces constitutes a problem of longstanding interest (see [5]–[13] for a sparse sampling). Our objective in this paper is to develop a fast forward solver, using discretized Gabor-based, high-frequency asymptotic, narrow-waisted Gaussian beam (GB) basis fields in conjunction with the complex source point (CSP) method for generating ray-like GB wave objects [1]–[3]. The Gabor-based narrow-waisted CSP-GB method has been applied previously [1]–[3] to two-dimensional (2-D) field propagation from extended nonfocused and focused one-dimensional (1-D) planar aperture distributions through layered

planar and cylindrical environments, and has been found to produce accurate, robust, and computationally efficient solutions over a broad range of problem parameters, provided that these do not violate the constraints imposed by the high-frequency asymptotic assumptions. Briefly, the robustness and reliability criteria are *pragmatic*, being based on the insensitivity of the result to “scramblings” (i.e., to different combinations) of the beam and lattice parameters within the constraint domain. Here, we extend this method to 1-D-aperture-excited 2-D field scattering from, and transmission through, a 1-D moderately rough arbitrary interface between two dielectric media. The resulting algorithm for radiated and scattered field synthesis by GB recombination is found to perform as in [1]–[3], but now subject to new restrictions that are stated, as necessary, in the appropriate sections of this paper.

The rest of this paper is organized as follows. In Section II, we summarize the rigorous, self-consistent Gabor-based Gaussian beam algorithm for a general aperture field distribution and the ensemble of paraxially approximated narrow-waisted CSP beams that this excitation generates [1]. Section III deals with the preliminary (canonical) problem of beam reflection from, and transmission through, a curved interface between two homogeneous dielectrics [14]. These constituents have been used previously for beam tracking through planar and curved layered dielectric configurations [2], [3]. In Section IV, we extend the algorithm to the new and more challenging problem of reflection and transmission of the plane-aperture-excited field in the presence of a moderately rough interface separating two homogeneous semi-infinite dielectric media. Extensive numerical simulations calibrate the algorithm within clearly stated constraints and highlight the role of certain critical parameters. Conclusions follow in Section V.

II. INCIDENT FIELD FROM AN EXTENDED APERTURE

A. Problem Statement

Consider a two-dimensional problem where a y -directed electric field with implicit time-harmonic dependence $\exp(-i\omega t)$ and spatial distribution $f(x)$ is assumed to occupy the aperture region $|x| \leq d/2$ at $z = z_A$ in free space, as depicted in Fig. 1

$$\mathbf{E}^{\text{inc}}(x, z_A) = f(x)\mathbf{u}_y, \quad |x| \leq d/2, \quad z = z_A. \quad (1)$$

Boldface quantities denote vectors and \mathbf{u} denotes a unit vector. The resulting (TM polarized) EM field radiated into the half-space $z < z_A$ can be expressed as a superposition of line-source generated fields (Kirchhoff integration) [15]

$$\mathbf{E}^{\text{inc}}(x, z) = \frac{i}{2} \int_{-d/2}^{d/2} f(x') \frac{\partial}{\partial z} H_0^{(1)}(k_0 R) dx' \mathbf{u}_y \quad (2)$$

$$\mathbf{H}^{\text{inc}} = \frac{1}{i\omega\mu_0} \nabla \times \mathbf{E}^{\text{inc}} = H_x^{\text{inc}} \mathbf{u}_x + H_z^{\text{inc}} \mathbf{u}_z \quad (3)$$

where $k_0 = \omega\sqrt{\epsilon_0\mu_0} = 2\pi/\lambda_0$ is the free-space wavenumber, λ_0 is the free-space wavelength, $H_0^{(1)}(\cdot)$ is the zeroth-order Hankel function of the first kind (line source Green's function), and

$$R = \sqrt{(x - x')^2 + (z - z_A)^2}. \quad (4)$$

Fig. 2. Discretized phase space lattice. Spatial shift indexes m identify GB launch points at $x = mL_x$. Spectral shift indexes n identify linearly phased GB tilts at $k_x = n\beta_x$.

Because of the polarization assumed in (1), all fields can be generated from the scalar $E = E_y$ component, so that the vector notation will be dropped from here on. Alternatively, by spectral plane wave superposition, one obtains [15]

$$E^{\text{inc}}(x, z) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{f}(k_x) \exp[i(k_x x + k_z z)] dk_x \quad (5)$$

where

$$\hat{f}(k_x) = \int_{-\infty}^{\infty} f(x) \exp(-ik_x x) dx \quad (6)$$

is the Fourier spectrum of $f(x)$, k_x is the x -domain wavenumber, and

$$k_z = \sqrt{k_0^2 - k_x^2}, \quad \text{Im}(k_z) \geq 0 \quad (7)$$

is the longitudinal (z -domain) wavenumber.

B. Gabor Beam Discretization

1) *Aperture Field*: The aperture field $f(x)$ is to be parameterized in terms of Gaussian basis functions via the rigorous self-consistent Gabor series representation [1], [15]–[19]

$$f(x) = \sum_{m,n=-\infty}^{\infty} A_{mn} w(x - mL_x) \exp(in\beta_x x) \quad (8)$$

where $w(x)$ represents the normalized Gaussian window function

$$w(x) = \left(\frac{\sqrt{2}}{L_x} \right)^{1/2} \exp[-\pi(x/L_x)^2], \quad \int_{-\infty}^{\infty} w^2(x) dx = 1. \quad (9)$$

This representation places the aperture distribution on a discretized (x, k_x) phase space lattice (see Fig. 2), with spatial and spectral shifts tagged by the indexes m and n , respectively. Spatial and spectral periods are related by the self-consistency relation (configuration-spectrum tradeoff) [16], [17]

$$L_x \beta_x = 2\pi. \quad (10)$$

As observed in [15] and [19], the Gaussian window provides the best occupation of the phase space. The expansion coefficients A_{mn} in (8) can be computed by introducing an auxiliary function $\gamma(x)$ defined through the *biorthogonality* condition [16], [17]

$$\int_{-\infty}^{\infty} w(x) \gamma^*(x - mL_x) \exp(-in\beta_x x) dx = \delta_m \delta_n \quad (11)$$

where $*$ denotes the complex conjugate and $\delta_q = 1$ for $q = 0$ and $\delta_q = 0$ for $q \neq 0$. The expansion coefficients can be written as [16], [17]

$$A_{mn} = \int_{-\infty}^{\infty} f(x) \gamma^*(x - mL_x) \exp(-in\beta_x x) dx. \quad (12)$$

For Gaussian windows, the biorthogonal function can be computed explicitly [16], [17] but will not be required in what follows later on.

2) *Radiated Field*: The initial distribution surrounding each lattice point in Fig. 2 generates a Gaussian beam that is launched from m -indexed locations and tilted according to n -indexed locations. The radiated incident field in the half-space $z < z_A$ [see (2)] therefore admits via (8) a similar discretized representation (we follow the notation in [1]; however, there are some sign changes with respect to [1] since here we assume propagation into the *negative* half-space $z < z_A$)

$$E^{\text{inc}}(x, z) = \sum_{m,n=-\infty}^{\infty} A_{mn} B_{mn}(x, z) \quad (13)$$

where the beam functions $B_{mn}(x, z)$ are expressed by Gabor-weighted line-source superposition

$$B_{mn}(x, z) = \frac{i}{2} \int_{-d/2}^{d/2} w(x' - mL_x) \cdot \exp(in\beta_x x') \frac{\partial}{\partial z} H_0^{(1)}(k_0 R) dx' \quad (14)$$

with R being defined in (4). By saddle point methods, the integral in (14) (or its spectral counterpart) can be evaluated asymptotically in the beam *paraxial far zone*, yielding the following *complex source point approximation* [2], [3]:

$$B_{mn}(x, z) \sim ik_0 2^{5/4} \left(\frac{L_x}{8\pi k_0 \tilde{R}_{mn}} \right)^{1/2} \cdot \exp \left\{ i \left[k_0 \left(\tilde{R}_{mn} + ib \right) + \pi/4 \right] \right\} \frac{(z - \tilde{z}'_{mn})}{\tilde{R}_{mn}} \quad (15)$$

with \tilde{R}_{mn} representing the *complex distance* between the observer at $P = (x, z)$ and the CSP

$$\tilde{P}'_{mn} = (\tilde{x}'_{mn}, \tilde{z}'_{mn}) = (mL_x + ib \sin \theta_n, z_A - ib \cos \theta_n) \quad (16)$$

$$\tilde{R}_{mn} = \overline{P \tilde{P}'_{mn}} = \sqrt{(x - \tilde{x}'_{mn})^2 + (z - \tilde{z}'_{mn})^2}. \quad (17)$$

In accord with the radiation condition, the square root in (17) is defined by $\text{Re}(\tilde{R}_{mn}) \geq 0$. Here and henceforth, the tilde \sim identifies CSP-generated complex quantities. The displacement parameter b (equal to the Fresnel length) is related to the beam lattice period L_x and the beam axis angle θ_n via [2]

$$b = (L_x \cos \theta_n)^2 / \lambda_0, \quad \theta_n = \sin^{-1}(n\lambda_0 / L_x). \quad (18)$$

Equation (15) is valid in the paraxial far-zone of each beam, $|\tilde{R}_{mn}| \gg b$. As the tilt index n increases, the beam tilt angle θ_n can become complex ($|n| > L_x / \lambda_0$), whence the corresponding beams become *evanescent*.

C. Narrow-Waisted Beams

In the following, we shall focus on nontilted ($n = 0$) *narrow-waisted* beams ($L_x \lesssim \lambda_0 \ll d$), which, as demonstrated in [1]–[3], have several attractive features. First, the Gabor coefficients A_{mn} in (13) can be effectively estimated by *sampling* the aperture field distribution at the lattice points $x = mL_x$, thus avoiding the time-consuming integration in (12) [1]

$$A_{mn} \approx \begin{cases} (L_x / \sqrt{2})^{1/2} f(mL_x), & n = 0 \\ 0, & n \neq 0. \end{cases} \quad (19)$$

Under this approximation, the tilted ($n \neq 0$) beams in the Gabor expansion, which here generate evanescent “far fields” [complex θ_n in (18)], are ignored. Second, for narrow-waisted beams, the CSP paraxial far-zone approximation (15) can be invoked at moderate distance; thus their *superposition* can furnish accurate results even in the *near zone* of the *aperture*. Third, as has been shown in [2] and [3], interaction of narrow-waisted beams with an environment can be implemented effectively by tracking the *complex ray* fields and recombining them at the observer, subject to constraints that are elucidated in the examples below.

D. Illustrative Examples

A thorough analysis of the accuracy and computational features of the *narrow-waisted* beam algorithm can be found in [1]. Here, we merely summarize relevant results. Referring to Fig. 1, we consider a linearly phased cosine-tapered aperture field distribution

$$f(x) = \begin{cases} \cos(\pi x / d) \exp(ik_0 \nu x), & |x| \leq d/2 \\ 0, & |x| > d/2 \end{cases} \quad (20)$$

where d is the aperture width and $\nu = \sin^{-1}(\varphi)$, with φ denoting the tilt angle of the main radiation lobe with respect to the z -axis. A special case (nonphased cosine, $\nu = 0$) is used in the rough interface simulation in Section IV-B. Fig. 3 shows the normalized magnitude of the exact Gabor coefficients [computed through numerical integration of (12)] as a function of the shift and tilt indexes (m, n) for narrow-waisted beams ($L_x = 0.0125d$). As one can see, the essential contribution comes from the nontilted beams, whose coefficient distribution closely matches the aperture field profile.

The beam-computed and reference near-zone *radiated* fields, which are obtained from (13) [with (15) and (19)], and via numerical evaluation of the Kirchhoff integral in (2), respectively, are shown in Fig. 4(a) for $\nu = 0.5$. Although based on the paraxial far-zone approximation in (15) for the beam propagators, the accuracy is quite good even in the near zone of the aperture (80 beams were used in this simulation). In the absence of phasing ($\nu = 0$), considerably coarser sampling is adequate. As shown in Fig. 4(b), even a beam lattice period $L_x = 0.1d$ (i.e., ten beams) yields accurate synthesis. Coarse sampling also works for linearly phased apertures if propagation-matched *tilted* basis beams are used [20]. The stated number of beams in these simulations was arrived at via the pragmatic “scramblings” test, i.e., when the result remains insensitive to variations in the beam/lattice combinations.

Fig. 3. Linearly phased cosine-tapered aperture field in (20) ($d = 10\lambda_0$, $\nu = 0.5$). Exact normalized Gabor coefficient magnitudes $|A_{mn}/A_{00}|$ in (12) evaluated numerically ($L_x = 0.0125d = 0.125\lambda_0$). Tilted ($n \neq 0$) beams are evanescent.

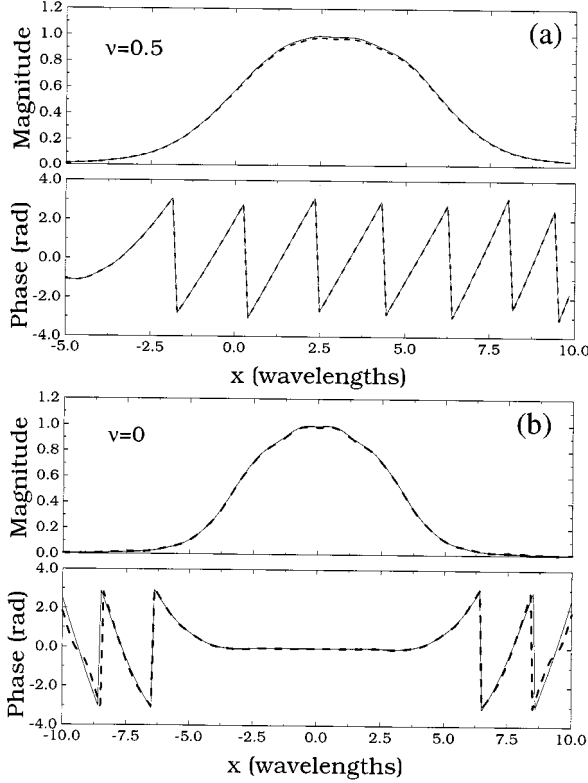

Fig. 4. Cosine-tapered aperture field in (20) ($d = 10\lambda_0$): Radiated near-zone field with $z_A = 10\lambda_0$, $z_{obs} = 5\lambda_0$. (a) $\nu = 0.5$, $L_x = 0.0125d = 0.125\lambda_0$ (i.e., 80 beams). (b) $\nu = 0$, $L_x = 0.1d = \lambda_0$ (i.e., ten beams). (—) Reference solution [Kirchhoff integration in (2)]. (---) Beam-computed from (13), with (15) and (19).

III. REFLECTION FROM AND TRANSMISSIONS THROUGH A SMOOTHLY CURVED DIELECTRIC INTERFACE: CANONICAL PROBLEM

A. Problem Strategy

Before considering the interaction of the beam-based incident field in Section II with the rough surface profile sketched in

Fig. 5. Beam reflection from a curved dielectric interface. α_s = real departure angle of incident beam axis with respect to the x -axis; α_r = real departure angle of reflected beam axis with respect to the x -axis; and θ_i = real incidence/reflection angle with respect to the surface normal N at P_{i0} ; r_c = surface radius of curvature at P_{i0} .

Fig. 1, we treat the canonical problem of interaction with a smoothly curved portion of that profile as shown in Figs. 5 and 6.

The beam-based synthesis of the reflected and transmitted fields can be constructed by propagating each of the incident narrow-waisted basis beams in Sections II-B and -C through the environment and recombining thereafter. Because the asymptotic basis beams are parameterized in terms of a source point in the complex coordinate space, they propagate in complex space along *complex* ray trajectories, which yield only a *single* physical point at the real space observer. This renders the field evaluation computation intensive. However, for narrow-waisted beams, one may utilize a paraxial approximation scheme, which leads to *almost real* ray tracing [3], [14] that is only slightly different from (and even computationally cheaper than) standard ray tracing from the Kirchhoff integration (2) in *real* configuration space.

B. Reflected Field

The problem geometry is illustrated in Fig. 5. An incident Gaussian beam is generated by a CSP at

$$\tilde{P}_s = (x_s + ib \cos \alpha_s, z_s + ib \sin \alpha_s) \quad (21)$$

with α_s being the *real* departure angle of the incident beam axis with respect to the x -axis. As shown in [14], for electrically large and smooth scatterers, and when the observation point $P = (x, z)$ lies in the paraxial region of the reflected beam [$\Delta \ll (|\tilde{F}_{r0}P_0|^2 + b^2)^{1/2}$ in Fig. 5], the reflected field can be approximated in terms of the on-axis field (at P_0) and a complex phase correction. Denoting the on-axis parameters by the subscript zero, one finds for the y -directed electric field [14]

$$\begin{aligned} E^{refl}(P) &\approx E^{refl}(P_0)|_{\tilde{P}_i=P_{i0}} \exp(i k_0 \tilde{\delta}_p) \\ &= \Gamma E^{inc}(P_{i0}) \left(\frac{\tilde{f}_{r0}}{\tilde{R}_0} \right)^{1/2} \exp[i k_0 (L_{r0} + \tilde{\delta}_p)] \end{aligned} \quad (22)$$

where (see Fig. 5)

$$\tilde{R}_0 = \overline{\tilde{F}_{r0}P_0}, \quad L_{r0} = \overline{P_{i0}P_0} \quad (23)$$

and $\tilde{\delta}_p$ is the complex phase correction

$$\tilde{\delta}_p = \tilde{R} - \tilde{R}_0, \quad \tilde{R} = \overline{\tilde{F}_{r0}P}. \quad (24)$$

Moreover, $\tilde{F}_{r0} = (\tilde{x}_{fr0}, \tilde{z}_{fr0})$ is the *complex* virtual focus obtained via analytic continuation of the standard ray-optical formulas (see [21, p. 169]), but approximating the *complex* incidence point \tilde{P}_i by the *real* beam-axis incidence point $P_{i0} = (x_{i0}, z_{i0})$

$$\tilde{x}_{fr0} = x_{i0} - \tilde{f}_{r0} \cos \alpha_r, \quad \tilde{z}_{fr0} = z_{i0} - \tilde{f}_{r0} \sin \alpha_r \quad (25)$$

$$\tilde{f}_{r0} = \frac{\tilde{L}_{i0} r_c \cos \theta_i}{2\tilde{L}_{i0} + r_c \cos \theta_i}, \quad \tilde{L}_{i0} = \overline{\tilde{P}_s P_{i0}}. \quad (26)$$

Here, α_r is the real departure angle of the reflected beam axis with respect to the x -axis, r_c is the curvature radius at P_{i0}

$$r_c = -\frac{[1 + (h'(x_{i0}))^2]^{3/2}}{h''(x_{i0})}, \quad ' \equiv d/dx \quad (27)$$

and Γ is the TM plane-wave reflection coefficient

$$\Gamma = \frac{\cos \theta_i - \sqrt{\epsilon_r - \sin^2 \theta_i}}{\cos \theta_i + \sqrt{\epsilon_r - \sin^2 \theta_i}} \quad (28)$$

where ϵ_r is the dielectric relative permittivity and θ_i is the real incidence angle with respect to the surface normal N at P_{i0} .

As shown in [14], this corresponds to tracing a ray along a *complex* trajectory from the CSP at \tilde{P}_s to the intersection of the *real* beam axis with the *real* surface; from there, the path to the observer proceeds entirely in *real* configuration space, along the beam axis. Also presented in [14] are further corrections, obtained by expanding the analytic continuation of the reflection coefficient Γ in (28) and of the divergence coefficient

$$\tilde{D}_r = \left[\frac{(\overline{\tilde{P}_s \tilde{P}_i} + \overline{\tilde{P}_i P}) r_c \cos \tilde{\theta}_i}{2\overline{\tilde{P}_s \tilde{P}_i} \overline{\tilde{P}_i P} + (\overline{\tilde{P}_s \tilde{P}_i} + \overline{\tilde{P}_i P}) r_c \cos \tilde{\theta}_i} \right]^{1/2} \quad (29)$$

$\tilde{\theta}_i \equiv \theta_i|_{P_{i0}=\tilde{P}_i}$

in Taylor series about their on-axis values. Actually, these corrections are more cumbersome to generate; we obtained acceptable results by using only the phase correction in (24). Multiple reflections can be incorporated by iterating (22) whereby [with proper definition of the square root in (17)] the complex focus determined at each iteration becomes the phase reference for the next iteration (see Appendix A). Again, apart from the complex ray connecting the CSP to the first real incidence point, the multihop path to the observer proceeds entirely in *real* configuration space along the beam axes, and the phase correction is applied only to the last beam segment that reaches the observer.

C. Transmitted Field

The same considerations applied to the transmitted field (see Fig. 6) yield [14]

$$\begin{aligned} E^{tr}(P) &\approx E^{tr}(P_0) \big|_{\tilde{P}_i=P_{i0}} \exp(ik\tilde{\delta}_p) \\ &= TE^{\text{inc}}(P_{i0}) \left(\frac{\tilde{f}_{t0}}{\tilde{R}_0} \right)^{1/2} \exp \left[ik_0 (L_{t0} + \sqrt{\epsilon_r} \tilde{\delta}_p) \right] \end{aligned} \quad (30)$$

Fig. 6. Beam transmission through a curved dielectric interface. α_R and θ_R are the refracted (transmitted) real departure angles with respect to the x -axis and the surface normal N at P_{i0} , respectively.

where $k = k_0 \sqrt{\epsilon_r}$ and

$$\tilde{R}_0 = \overline{\tilde{F}_{t0} P_0}, \quad L_{t0} = \overline{P_{i0} P_0} \quad (31)$$

$$\tilde{\delta}_p = \tilde{R} - \tilde{R}_0, \quad \tilde{R} = \overline{\tilde{F}_{t0} P} \quad (32)$$

$$\tilde{F}_{t0} = (x_{i0} + \tilde{f}_{t0} \cos \alpha_R, z_{i0} + \tilde{f}_{t0} \sin \alpha_R) \quad (33)$$

$$\tilde{f}_{t0} = \frac{\tilde{L}_{i0} r_c \cos \theta_R}{(\Omega - 1)\tilde{L}_{i0} + \Omega r_c \cos \theta_i}, \quad \Omega = \frac{\cos \theta_i}{\sqrt{\epsilon_r} \cos \theta_R} \quad (34)$$

$$T = 1 + \Gamma \quad (35)$$

with α_R denoting the real departure angle of the transmitted beam axis with respect to the x -axis and θ_R denoting the refraction angle, with respect to the surface normal N at P_{i0} , according to Snell's law

$$\sin \theta_i = \sqrt{\epsilon_r} \sin \theta_R. \quad (36)$$

As before, this approximation corresponds to tracing a complex ray from the CSP to the real incidence point and then a real ray to the observer [14]. Note that in the presence of a slightly lossy dielectric as in Fig. 8, the refraction angle θ_R becomes complex. In that case, we still use a real refracted ray, propagating along the direction $\text{Re}(\theta_R)$. Multiple reflections/transmissions can be handled by iterating and combining (22) and (30), following the guidelines given in Section III-B.

IV. REFLECTION FROM AND TRANSMISSION THROUGH A MODERATELY ROUGH DIELECTRIC INTERFACE

We now address the “real problem” geometry in Fig. 1, using the building blocks of Sections II-B, II-C, and III.

A. The Multiply Reflected/Transmitted Beam Algorithm

The main steps of the proposed algorithm can be summarized as follows.

- 1) *Aperture Field Discretization.* The narrow-waisted CSP algorithm (15)–(19) in Sections II-B and -C is applied to the given aperture field distribution and yields the Gabor-weighted beam amplitudes.
- 2) *Beam-Axes Tracing.* The beam axes follow real-ray trajectories in real configuration space. For each beam

launched at the aperture plane, the axis trajectories after intersection at an interface are governed by Snell's laws of reflection and transmission (see Figs. 5 and 6). The hierarchy of possible multiple (reflection/transmission) bifurcations at each encounter with the *rough* interface can be organized formally through use of a binary-tree data structure [22], whose *nodes* contain the relevant data (i.e., incidence point, departure angle, etc.). However, in our applications here, we shall rely primarily on the first, and possibly also the second, bifurcation.

- 3) *Beam Parameter Computation.* Having determined the beam axis topology, the other relevant parameters for each beam segment (e.g., reflection/transmission coefficients, complex foci, phase lag) are computed recursively, starting from the initial complex source point and progressively scanning the binary tree (see Appendix A).
- 4) *Beam Field Computation.* Each reflected/transmitted Gabor-weighted beam field contribution at the observer is computed via the quasiray paraxial approximations (22)–(28) and (30)–(36) described in Section III. As already stated, in the presence of multiple interactions, the complex phase correction is applied only to the last beam segment that reaches the observer (see Appendix A).
- 5) *Beam Summation for Total Field.* The individual reflected/transmitted beam contributions are recombined to yield the total field at the observer.

In principle, the above multiple interaction algorithm is able to account for possible evanescent contributions (total reflection). We have not explored this aspect so far and have, in fact, restricted the problem conditions in the numerical tests of Section IV-B so that total reflection does not occur. Also excluded are near-grazing incidence contributions, which require more sophisticated propagation models than those in Section III. Note also that in [2], [3], the narrow-waisted beam algorithm is applied to propagation through planar and circular cylindrical dielectric layers where the beam tracing can be performed analytically; in our problem, due to the irregular form of the interface profile $h(x)$ (see Fig. 1), a numerical procedure is required.

B. Example Problems and Numerical Results

In the problem geometry of Fig. 1, the TM-polarized field generated by the nonphased cosine-tapered aperture field distribution in (20) (with $\nu = 0$) is assumed to impinge from free space onto a moderately rough interface described by the continuous function $h(x)$, which in the examples below is parameterized by a quartic-spline [23]

$$h(x) = \sum_{n=-4}^{N_h-1} c_n s_4(x - x_n), \quad x_{\min} \leq x \leq x_{\max} \quad (37)$$

$$x_n = x_{\min} + n\Delta x, \quad \Delta x = (x_{\max} - x_{\min})/N_h \quad (38)$$

with $s_4(\cdot)$ representing the standard quartic B-spline basis function (Fig. 7) [23]. Because of this parameterization, most of the beam tracing computational tasks (solution of fourth-degree algebraic equations) can be performed *analytically*. The aperture width is adjusted so as to illuminate most of the re-

Fig. 7. Quartic B-spline basis function $s_4(x)$.

Fig. 8. Rough surface geometry and parameters. Relative permittivity: $\epsilon_r = 3 + i0.05$; maximum slope: 34° ; minimum curvature radius: $4.2\lambda_0$; maximum height: $5.88\lambda_0$. The chosen permittivity models a class of realistic soil conditions.

gion of interest, with edge effects deemphasized due to the aperture profile tapering. Since we intend to apply the beam method to detection and identification of buried objects, the dielectric half-space parameters have been chosen to simulate soil conditions [24]. The reflected and transmitted fields for this configuration have been computed via the beam algorithm detailed in Sections II and III and compared with a reference solution obtained by the Leviatan–Boag multifilament current method [25]. Although this method was introduced in [25] for cylindrical scatterers, its application to the rough surface geometry is justified in Appendix B. Since beam superposition is a high-frequency (HF) method, the rough surface parameters were adjusted so as to guarantee a minimum curvature radius of about 4.2 free-space wavelengths and a maximum slope of about 34° (see Fig. 8). This places the wave dynamics well within the range for HF asymptotic localization. Note that the dielectric is slightly lossy so that the remarks in Section III-C apply. It should be mentioned that we have previously applied the algorithm to reflection from a perfectly conducting sinusoidal profile and have calibrated its range of validity there [26]. The results from this test case have guided our choice of problem parameters here.

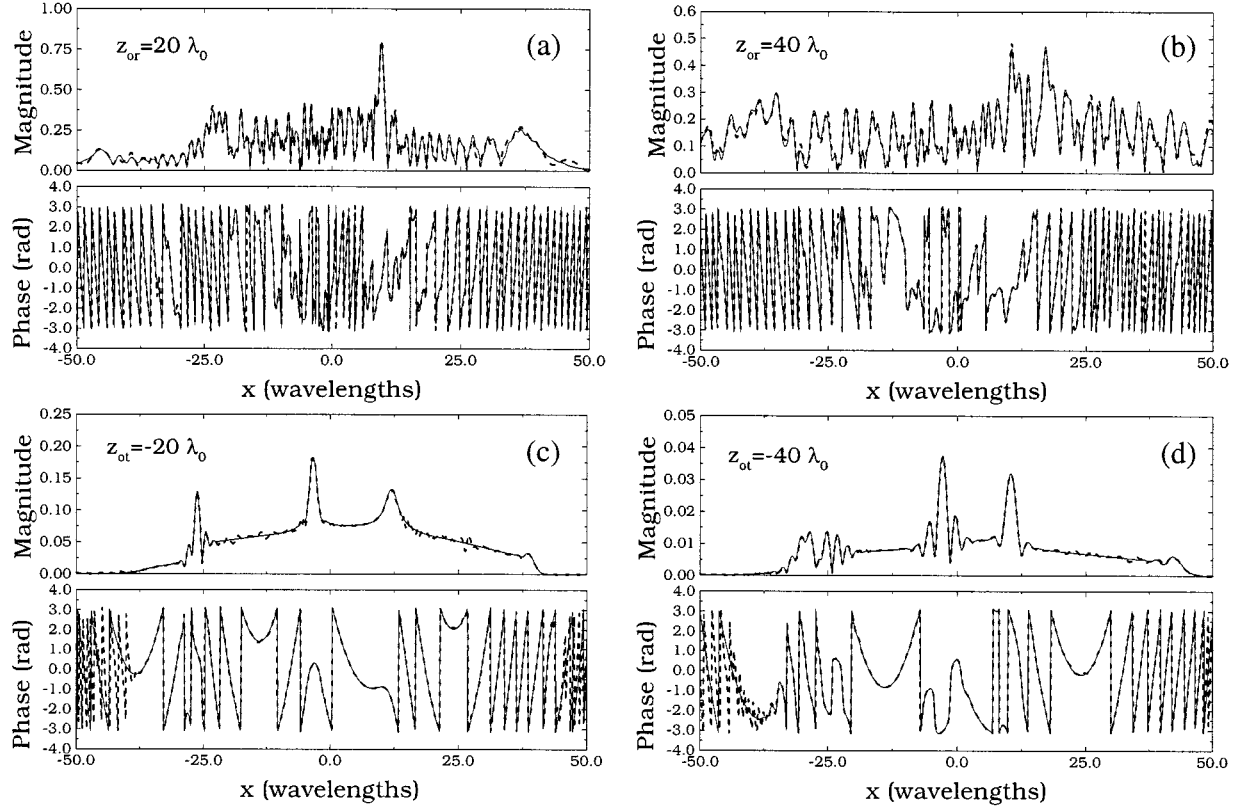

Fig. 9. Beam-computed reflected/transmitted fields and Leviatan-Boag reference solution in various observation planes. Parameters as in Fig. 8. Aperture width: $d = 80\lambda_0$; aperture height: $z_A = 6.4\lambda_0$ (i.e., $0.52\lambda_0$ above maximum profile height); beam lattice period: $L_x = 0.0125d = \lambda_0$ (i.e., 80 beams). (a) Reflected field at $z_{or} = 20\lambda_0$. (b) Reflected field at $z_{or} = 40\lambda_0$. (c) Transmitted field at $z_{ot} = -20\lambda_0$. (d) Transmitted field at $z_{ot} = -40\lambda_0$. (—) Reference solution and (---) beams.

In Fig. 9, for a fixed beam-lattice configuration and the problem parameters in Fig. 8, the beam-computed reflected and transmitted fields at various observation planes are compared with the reference solution. Here, the aperture is located $0.52\lambda_0$ away from the nearest portion of the interface profile, thereby ensuring that the *individual* narrow-waisted paraxial GBs are collimated sufficiently to have them interact *locally* with the irregular surface. We found that in order to obtain robust and accurate predictions, the aperture distance to the profile should be no larger than a wavelength. As in [26], good agreement is verified for the beam/lattice parameters listed in the figure captions. The accuracy of the scattered/transmitted field synthesis improves for *greater observation distance* because of the *collective* behavior of the beams in the far-zone paraxial approximation. The agreement is satisfactory even at moderate observation distances, despite some slight local deviations. As in [1]–[3], numerical insensitivity to beam/lattice parameter scramblings is taken as a pragmatic performance criterion for robustness of the algorithm (see Fig. 10). This feature permits *a priori* accuracy assessments when reference solutions are not available; note that the pragmatic scrambling criterion used here aims at an *adequate* number of beams, without any attempt to minimize that number. For the nonphased aperture example, we found the best tradeoff between accuracy and computational cost for $L_x \sim \lambda_0$. A finer sampling may, however, be required for phased aperture field distributions. It should be emphasized that the accuracy deteriorates with increasing distance of the aperture from the nearest point on the surface profile. As noted

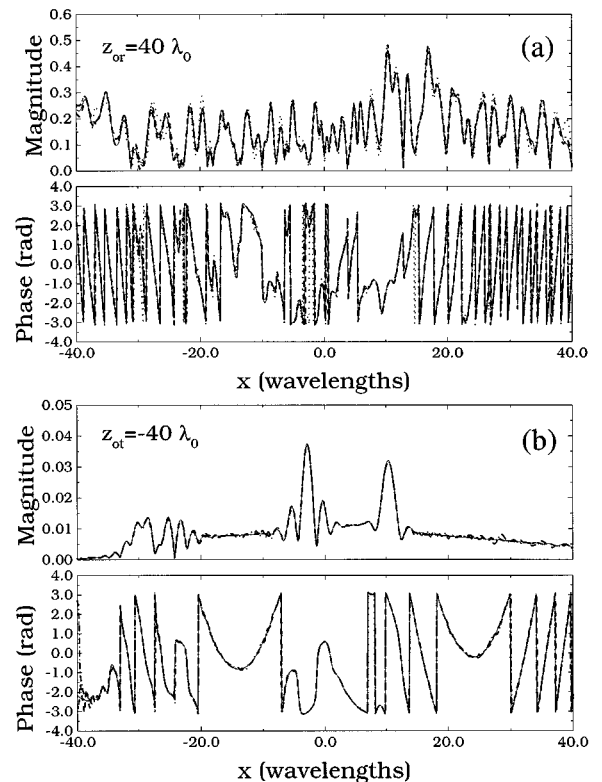

Fig. 10. (a) As in Fig. 9(b), but with various beam lattice periods. (b) As in Fig. 9(d), but with various beam lattice periods. (—) Reference solution; (·····) 134 beams ($L_x = 0.0075d$); (---) 80 beams ($L_x = 0.0125d$); and (-·-·-) 58 beams ($L_x = 0.0175d$).

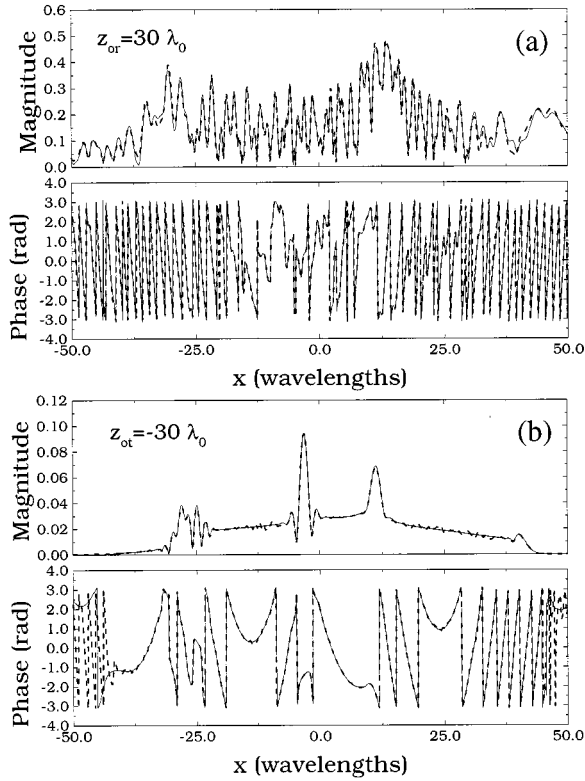

Fig. 11. As in Fig. 9, but with aperture plane at $z_A = 35.9\lambda_0$. Multistep beam algorithm: i) Narrow-waisted beam discretization at $z = z_A$ with $L_x = 0.01d$ (i.e., 100 beams). ii) Beam-computed incident field projection onto a virtual aperture at $z_V = 6.4\lambda_0$ as in Fig. 9, to restore the local sampling capability of the surface profile by the individual basis beams. iii) Narrow-waisted beam decomposition at $z = z_V$ with $L_x = 0.0125d = \lambda_0$ (i.e., 80 beams) as in Fig. 9. iv) Beam-tracing paraxial-approximation scheme. (a) Reflected field at $z_{or} = 30\lambda_0$. (b) Transmitted field at $z_{ot} = -30\lambda_0$. The maximum height of the profile in Fig. 8 is $5.88\lambda_0$. (—) Reference solution and (---) beams.

above, to establish the scattered/transmitted field by local beam sampling of the interface profile, the aperture must be close enough to the surface so that the rapid spread of the beams at greater distances has not yet taken place. However, this is not a severe limitation, since, as shown in Fig. 11, it is possible to perform a two-step Gabor decomposition, i.e., projecting the beam-computed radiated field onto a virtual aperture (within a wavelength above the surface so as to restore the local sampling capability) and then again applying the (narrow-waisted) beam algorithm. The additional cost is computationally minimal because of the highly efficient evaluation of the Gabor coefficients for narrow-waisted beams [see (19)]. Even for relatively “low-frequency” geometries with critical dimensions on the order of a wavelength or less, the beam algorithm, though no longer *highly* accurate, may still be able to provide reasonably good predictions. For *small* radius of curvature portions on the roughness profile, this is demonstrated in Fig. 12, with the problem parameters given in the figure caption. Of course, each such excursion into the “low-frequency” range must be validated independently by the scrambling criterion, but it is worth noting that such attempts need not to be doomed to failure *a priori*. Although the beam algorithm performance assessments here are based on the single example depicted in Figs. 7 and 8, we emphasize that confidence in these assessments has been established by an extensive sequence of relevant prior

Fig. 12. Rough interface profile as in Fig. 8, but scaled so as to have maximum slope: 34° ; minimum curvature radius: $0.42\lambda_0$; maximum height: $0.588\lambda_0$. Beam-computed reflected/transmitted fields and Leviatan–Boag reference solutions. Aperture width: $d = 8\lambda_0$; aperture height: $z_A = 0.8\lambda_0$; beam lattice period: $L_x = 0.1d = 0.8\lambda_0$ (i.e., ten beams). (a) Reflected field at $z_{or} = 8\lambda_0$. (b) Transmitted field at $z_{ot} = -8\lambda_0$. (—) Reference solution and (---) beams.

numerical calibration experiments. In particular, we have found accurate results for moderate roughness with maximum slopes $\lesssim 40^\circ$ and (average) curvature radii larger than a wavelength, and for incidence directions far from grazing [$\nu \lesssim \sin 30^\circ$ in (20)]. We have also performed simulations for very high and low dielectric contrasts with $\text{Re}(\epsilon_r)$ ranging from 1.2 to 10 and $\text{Im}(\epsilon_r)$ up to 0.5; the quality of results was found to be similar to those for the case of Fig. 8. Concerning computing times, for the most expensive (two-step) implementation described in Fig. 11, we found about 9 ms to compute the field at a single position on a 500-MHz laptop; no particular effort was made to optimize the numerical code.

V. CONCLUDING REMARKS

A previously developed, rigorous, self-consistent, quasi-ray, narrow-waisted beam algorithm [1]–[3] has been reexamined and applied to the new problem of EM transmission and reflection in the presence of moderately rough surfaces.

The narrow-waisted beams are wave objects with very short collimation lengths and therefore act like *almost real* ray fields. The rigorous complex ray machinery that is required for arbitrary complex source point beams can thus be reduced to *almost real* ray asymptotics, which, however, avoids failures near caustics and other ray-field transition regions. Due to its rapid spreading, the paraxial approximations described in Section III are of little use for tracking a *single* narrow-waisted beam away

from an aperture into the far zone. However, as observed in [2] and [3], when treated *collectively* as an *ensemble*, each paraxial beam can be tracked locally to and from dielectric interfaces with large radius of curvature. Apart from the paraxial beam-tracing procedure, the computational complexity of the beam algorithm is $\mathcal{O}(N_b)$, with N_b being the number of beams in the expansion. In contrast to standard ray methods, time-consuming eigenray search for evaluating the field at a given observation point is avoided, and the beam tracing needs to be performed *only once* (phrased in another way, we are interested in reliably evaluating the actual field at the observer without worrying about which appropriately weighted individual beam contributions establish that field). The algorithm has been calibrated against a reference (full-wave) solution, and will be exploited as a fast forward solver in the interface profile estimation problem [4]. A two-step beam decomposition may be required when the aperture is “sufficiently far” from the scatterer. In this case, the computational complexity is of the same order as the physical optics (PO) Kirchhoff approximation for a dielectric interface. However, the beam algorithm usually allows a coarser discretization, so that N_b is typically smaller than the corresponding number of PO integration points in the Kirchhoff integral [see (2), but applied to integration along the interface profile] for specified accuracy. In addition, the beam algorithm is potentially able to accommodate multiple interactions in a simpler fashion. The algorithm can be extended to pulsed excitations [27].

APPENDIX A MULTIPLE REFLECTIONS

Consider an incident Gaussian beam generated by the CSP in (21). Denoting by $P_{i0}^{(j)} = (x_{i0}^{(j)}, z_{i0}^{(j)})$, $j = 1, \dots, N_r$, the real incidence points from which emerge the (real ray) reflected beam axes, and by $P_{i0}^{(N_r+1)} = P_0$ the orthogonal projection of the observation point P onto the axis of the $(N_r + 1)$ th beam that reaches the observer, the far-zone paraxial approximation (22) can be generalized as follows (implementing the procedure outlined at the end of Section III-B):

$$E^{refl}(P) \approx E^{inc}(P_{i0}^{(1)}) \exp\left(ik_0 \tilde{\delta}_p^{(N_r)}\right) \cdot \prod_{j=1}^{N_r} \Gamma^{(j)} \left(\frac{\tilde{f}_{r0}^{(j)}}{\tilde{R}_0^{(j)}} \right)^{1/2} \exp\left(ik_0 L_{r0}^{(j)}\right) \quad (39)$$

where

$$\tilde{R}_0^{(j)} = \overline{\tilde{f}_{r0}^{(j)} P_{i0}^{(j+1)}}, \quad L_{r0}^{(j)} = \overline{P_{i0}^{(j)} P_{i0}^{(j+1)}} \quad (40)$$

$$\tilde{f}_{r0}^{(j)} = \left(x_{i0}^{(j)} - \tilde{f}_{r0}^{(j)} \cos \alpha_r^{(j)}, z_{i0}^{(j)} - \tilde{f}_{r0}^{(j)} \sin \alpha_r^{(j)} \right) \quad (41)$$

$$\tilde{f}_{r0}^{(j)} = \frac{\tilde{L}_{i0}^{(j)} r_c^{(j)} \cos \theta_i^{(j)}}{2\tilde{L}_{i0}^{(j)} + r_c^{(j)} \cos \theta_i^{(j)}} \quad (42)$$

$$\tilde{L}_{i0}^{(1)} = \overline{\tilde{P}_s P_{i0}^{(1)}}, \quad \tilde{L}_{i0}^{(j)} = \overline{\tilde{f}_{r0}^{(j-1)} P_{i0}^{(j)}}, \quad j \geq 2 \quad (43)$$

$$r_c^{(j)} = - \frac{\left[1 + (h'(x_{i0}^{(j)}))^2 \right]^{3/2}}{h''(x_{i0}^{(j)})} \quad (44)$$

$$\Gamma^{(j)} = \frac{\cos \theta_i^{(j)} - \sqrt{\epsilon_r \sin^2 \theta_r^{(j)}}}{\cos \theta_i^{(j)} + \sqrt{\epsilon_r - \sin^2 \theta_r^{(j)}}} \quad (45)$$

$$\tilde{\delta}_p^{(N_r)} = \tilde{R}^{(N_r)} - \tilde{R}_0^{(N_r)}, \quad \tilde{R}^{(N_r)} = \overline{\tilde{f}_{r0}^{(N_r)} P}. \quad (46)$$

In the above expressions, $\theta_i^{(j)}$ and $\alpha_r^{(j)}$ represent the real incidence angle [with respect to the surface normal at $P_{i0}^{(j)}$] and the real reflected beam axis departure angle (with respect to the x -axis) at the j th reflection, respectively.

APPENDIX B REFERENCE SOLUTION

The multifilament–current method in [25] has been applied originally to scattering by, and transmission through, dielectric cylinders, but it can be easily adapted to smoothly irregular scatterers or moderately rough interfaces. The extension is based on the expansion of the internal and external unknown fields in terms of basis functions generated by suitably placed line sources. As in many numerical techniques, the unknown expansion coefficients are determined by solving a linear system obtained by enforcing the continuity boundary conditions of the tangential fields at selected points on the dielectric interface. In the resulting algorithm, the obtained numerical solution satisfies Maxwell’s equations by construction, and its convergence and consistency are controlled by monitoring the error (discontinuity) in the boundary conditions at the dielectric interface between the matching points [25]. In our simulations, we chose the relevant parameters so as to ensure a 0.01% maximum error in the boundary conditions.

Vincenzo Galdi (M'98) was born in Salerno, Italy, on July 28, 1970. He received the Laurea degree (*summa cum laude*) in electrical engineering and the Ph.D. degree in applied electromagnetics from the University of Salerno, Italy, in 1995 and 1999, respectively.

From April to December 1997, he held a Visiting Position in the Radio Frequency Division of the European Space Research & Technology Centre (ESTEC-ESA), Noordwijk, The Netherlands, where he was involved in developing CAD tools for microwave filters and phased-array antennas with coaxial excitation. In

September 1999, he received a European Union postdoctoral fellowship through the University of Sannio, Benevento, Italy. In October 1999, he became a Research Associate in the Department of Electrical and Computer Engineering, Boston University, Boston, MA, where he is currently working on wave-oriented imaging algorithms for landmine detection and classification. His research interests include analytical and numerical techniques for wave propagation in complex environments, path integrals, and stochastic resonance.

Dr. Galdi is the recipient of the 2001 International Union of Radio Science (URSI) "Young Scientist Award." He is a member of Sigma Xi.

Leopold B. Felsen (S'47–M'54–SM'55–F'62–LF'90) was born in Munich, Germany, on May 7, 1924. He received the B.E.E., M.E.E., and D.E.E. degrees from the Polytechnic Institute of Brooklyn, Brooklyn, NY, in 1948, 1950, and, 1952, respectively.

He emigrated to the United States in 1939 and served in the U.S. Army from 1943 to 1946. After 1952, he remained with the Polytechnic Institute of Brooklyn (now Polytechnic University), becoming a Professor in 1962 and University Professor in 1978. From 1974 to 1978, he was Dean of Engineering.

In 1994, he resigned from the full-time Polytechnic Faculty and became University Professor Emeritus. He is now a part-time Professor of Aerospace and Mechanical Engineering and Professor of Electrical and Computer Engineering at Boston University, Boston, MA. He is the author or coauthor of more than 300 papers and several books, including *Radiation and Scattering of Waves* (Englewood Cliffs, NJ: Prentice-Hall, 1973; Piscataway, NJ: IEEE Press, 1994). He is an Associate Editor of several professional journals and an editor of the *Wave Phenomena Series* (New York: Springer-Verlag). His research interests encompass wave propagation and diffraction in complex environments and in various disciplines, high-frequency asymptotic and short-pulse techniques, and phase-space methods with an emphasis on wave-oriented data processing and imaging.

Dr. Felsen is a member of Sigma Xi and a Fellow of the Optical Society of America and the Acoustical Society of America. He has held named Visiting Professorships and Fellowships at universities in the United States and abroad, including the Guggenheim in 1973 and the Humboldt Foundation Senior Scientist Award in 1981. In 1974, he was an IEEE Antennas and Propagation Society (APS) Distinguished Lecturer. He received the Balthasar van der Pol Gold Medal from the International Union of Radio Science (URSI) in 1975, an honorary doctorate from the Technical University of Denmark in 1979, the IEEE Heinrich Hertz Gold Medal for 1991, the APS Distinguished Achievement Award for 1998, the IEEE Third Millennium Medal in 2000 (nomination by APS), three Distinguished Faculty Alumnus Awards from Polytechnic University, and an IEEE Centennial Medal in 1984. He also has received Best Paper awards for several papers in which he was an author or coauthor. In 1977, he was elected to the National Academy of Engineering. He served on the APS Administrative Committee from 1963 to 1966 and as Vice Chairman and Chairman for both the United States (1966–1973) and the International (1978–1984) URSI Commission B.

David A. Castañón (S'68–M'79–SM'98) received the B.S. degree in electrical engineering from Tulane University, New Orleans, LA, in 1971 and the Ph.D. degree in applied mathematics from the Massachusetts Institute of Technology (MIT), Cambridge, in 1976.

From 1976 to 1981, he was a Research Associate with the Laboratory for Information and Decision Systems, MIT. From 1982 to 1990, he was Senior and Chief Research Scientist at Alphatech, Inc., Burlington, MA. Since 1990, he has been a Professor in the Department of Electrical and Computer Engineering, Boston University, Boston, MA. His research interests include stochastic control and estimation, optimization, and image processing.

Dr. Castañón served as a member of the Board of Governors of the IEEE Control Systems Society. He is also a member of AMS, SIAM, and INFORMS.

Narrow-Waisted Gaussian Beam Discretization for Short-Pulse Radiation From One-Dimensional Large Apertures

Vincenzo Galdi, *Member, IEEE*, Leopold B. Felsen, *Life Fellow, IEEE*, and David A. Castañón, *Senior Member, IEEE*

Abstract—In this paper, we develop a Gabor-based Gaussian Beam (GB) algorithm for representing two-dimensional (2-D) radiation from finite aperture distributions with short-pulse excitation in the time domain (TD). The work extends previous results using 2-D frequency-domain (FD) narrow-waisted Gaussian beams [1]. The FD algorithm evolves from the rigorous Kirchhoff integration over the aperture distribution, which is then parameterized via the discrete Gabor basis and evaluated asymptotically for high frequencies to furnish the GB propagators to the observer. The TD results are obtained by Fourier inversion from the FD and yield pulsed beams (PB). We describe the resulting TD algorithm for several aperture distributions, ranging from simple linearly phased (linear delay) to arbitrary time delay profiles; the latter accommodate the important case of focusing TD aperture fields. For modulated pulses with Gaussian envelopes, we compute accurate closed form analytic solutions, which have been calibrated against numerical reference data. Our results confirm that the previously established utility of the Gabor-based narrow-waisted FD-GB algorithm for radiation from distributed apertures [1] remains intact in the TD.

Index Terms—Gabor lattice representations, Gaussian beams (GBs), pulsed beam wavepackets.

I. INTRODUCTION

GAUSSIAN beams (GBs) have been used *conventionally* as *highly collimated* basis elements in a variety of frequency domain (FD) and time domain (TD) radiation, propagation and scattering scenarios, especially in the asymptotic high frequency (HF) regime. The bases can be continuous or discrete, the latter being anchored to a Gabor lattice in the (physical-domain)–(spectral domain) FD or TD phase space [2]–[10]. When applied to radiation from extended

GB-parameterized aperture distributions, the radiated fields at the observer are synthesized by summation over the individual basis beam contributions. When interacting with a complex propagation or scattering environment, the (localization) resolution capabilities of the GB algorithms are essentially on the order of the collimation width of the basis beams, which generally extends over many wavelengths. This is in contrast to HF ray-based algorithms that explore local properties of the environment, but have deficiencies due to failures in ray-optical transition regions near shadow boundaries, caustics, etc. A *nonconventional* form of the Gabor algorithm, which uses *narrow-waisted poorly collimated* basis beams, simulates ray-like behavior without the transition region failures of ray fields. In the FD, the collective effect of the narrow-waisted nonconventional Gabor-stacked basis beams has been shown capable of furnishing highly accurate and numerically efficient solutions for scattering by, or transmission through, complex environments irradiated by aperture distributions [11]–[14]; this renders the algorithm useful as an efficient forward solver for inverse scattering and reconstruction [15].

In this paper, we extend the FD Gabor-based narrow-waisted beam algorithm for radiation from extended apertures [1] to the TD. The initial Kirchhoff integration over the FD aperture distribution is parameterized via the discrete Gabor basis and reduced by high frequency asymptotics to furnish the GB propagators to the observer; the TD pulsed beam (PB) propagators are obtained by Fourier inversion from the FD. For insight into the analytic implications and physical interpretation of the FD-inverted integrals, various aperture distributions are analyzed, starting from linearly phased (linear delay) to arbitrary time delay profiles; the latter are illustrated by the important example of focusing TD aperture fields. Accurate and easily computable closed-form analytic solutions are obtained for modulated pulses with Gaussian envelopes and are calibrated against independently generated numerical reference data. These results confirm that the previously established utility of the Gabor-based narrow-waisted FD-GB algorithm for radiation from distributed apertures [1] remains intact in the time domain.

In the FD, it has been established that the GB basis beams can be tracked efficiently from the aperture through interactions with complex scattering environments [11]–[14] and are therefore useful forward solvers in inversion scenarios [15]. Interaction of the PB propagators with complex environments is presently under consideration.

The rest of this paper is organized as follows. Section II has a compact summary of the FD formulation and its asymptotic re-

duction for narrow-waisted basis beams; the results are applied to linearly phased apertures (which includes the nonphased special case). Section III is concerned with the inversion to the TD, treating in sequence space-time separable linear-delay and nonlinear-delay aperture field profiles. The analytic reduction of the GB inversion integrals for modulated Gaussian envelope pulsed beams (PB) is presented succinctly, with details relegated to several appendixes. Simplifying approximations are stated. The resulting constraints on the range of validity of the algorithms are assessed analytically and phrased concisely in terms of critical nondimensional estimators. Calibration/confirmation is implemented through a sequence of numerical tests and examples, including radiation from a cosine-tapered aperture distribution with nonlinear (quadratic) delay, which is tracked as the wavefield approaches, reaches, and propagates beyond, the focal plane. Snapshots in the examples are resolved in terms of spatial and temporal cuts that depict the spatial and temporal deformations along the propagation path of the pulsed wavefield. Conclusions are presented in Section IV.

II. FREQUENCY DOMAIN FORMULATION

We briefly summarize the frequency domain (FD) formulation, and refer the interested reader to [1]–[4], [11], [12] for details. We restrict ourselves to the 2-D (x, z) domain, with all configurational quantities independent on y . Excitation is specified as a y -directed electric field with implicit time-harmonic dependence $\exp(-i\omega t)$ and spatial distribution $F(x, \omega)$, which occupies the aperture region $|x| \leq d/2$ at $z = 0$

$$E_y(x, z = 0, \omega) = F(x, \omega), \quad |x| \leq d/2. \quad (1)$$

The aperture geometry is shown in Fig. 1. The resulting (TM polarized) electromagnetic (EM) field radiated into the half-space $z > 0$ can be expressed by line-source superposition (Kirchhoff integration) in physical space

$$E_y(x, z, \omega) = -2 \frac{\partial}{\partial z} \int_{-d/2}^{d/2} F(x', \omega) G_{2D}(kR) dx' \quad (2)$$

$$\mathbf{H} = \frac{1}{i\omega\mu_0} \nabla \times E_y \mathbf{u}_y = H_x \mathbf{u}_x + H_z \mathbf{u}_z \quad (3)$$

where

$k = \omega\sqrt{\epsilon_0\mu_0} = 2\pi/\lambda$ free-space wavenumber, with λ as the wavelength;

$\mathbf{u}_0^{(1)}(\cdot)$ denotes a unit vector; zeroth order Hankel function of the first kind;

and (in accord with the radiation condition)

$$R = \sqrt{(x - x')^2 + z^2} \geq 0. \quad (4)$$

In the remainder of this section, the ω dependence in E_y and F will be omitted in the notation. Equation (2) is derived using the free-space 2-D Green's function $G_{2D}(R)|_{z'=0}$ to simulate an equivalent magnetic line dipole current distribution on an electric wall boundary.

Fig. 1. Aperture geometry, global coordinates and beam coordinates for a tapered linearly phased aperture field distribution. FD: $F(x, \omega) = P(\omega)g(x) \exp(ikx \sin \theta_A)$ [see (29)]. TD: $f(x, t) = g(x)p(t - c^{-1}x \sin \theta_A)$ [see (28)].

Fig. 2. Discretized Gabor lattice in the (x, k_x) phase space, where k_x is the x -domain wavenumber. $n = \text{const.}$: spatially displaced beams centered at $x_m = mL_x$, with fixed phase gradient (beam tilt) $(n\beta_x)$; $m = \text{const.}$: spectrally displaced beams with beam tilts $(n\beta_x)$ at fixed location x_m .

A. FD Beam Discretization

1) *Aperture Field*: The aperture field $F(x)$ is to be parameterized in terms of GB basis functions via the rigorous self-consistent Gabor series representation [16], [17]

$$F(x) = \sum_{m,n=-\infty}^{\infty} A_{mn} w(x - mL_x) \exp(in\beta_x x) \quad (5)$$

where $w(x)$ represents the normalized Gaussian window (initial beam profile)

$$w(x) = \left(\frac{\sqrt{2}}{L_x} \right)^{1/2} \exp[-\pi(x/L_x)^2] \quad (6)$$

$$\int_{-\infty}^{\infty} w^2(x) dx = 1.$$

This representation places the beam basis functions on a discretized (x, k_x) phase-space lattice (see Fig. 2), on which each lattice point gives rise to a GB, whose spatial and spectral (beam tilt) shifts are tagged by the indexes m and n , respectively. Spatial and spectral periods are related by the self-consistency relation (configuration-spectrum tradeoff) $L_x\beta_x = 2\pi$ [16], [17]. The expansion coefficients in (5) can be computed by introducing an auxiliary *bi-orthogonal* function $\gamma(x)$ [16], [17]

$$A_{mn} = \int_{-\infty}^{\infty} F(x) \gamma^*(x - mL_x) \exp(-in\beta_x x) dx \quad (7)$$

but as shown below, our subsequent use of narrow-waisted beams avoids the cumbersome computation of γ and numerical implementation of (7). Combining (2) and (5) yields the Gabor lattice representation of the aperture field.

2) *Radiated Field*: The corresponding Gabor lattice representation for the field radiated into the half-space $z > 0$ is given by [1]

$$E_y(x, z) = \sum_{m, n=-\infty}^{\infty} A_{mn} B_{mn}(x, z) \quad (8)$$

where the beam functions $B_{mn}(x, z)$ are expressed by Gabor-weighted line-source superposition

$$B_{mn}(x, z) = -\frac{i}{2} \int_{-d/2}^{d/2} w(x' - mL_x) \times \exp(in\beta_x x') \frac{\partial}{\partial z} H_0^{(1)}(kR) dx' \quad (9)$$

R being defined in (4). By saddle point methods, the integral in (9) (or its spectral counterpart) can be evaluated asymptotically in the beam *paraxial far zone*, yielding the following *complex source point* (CSP) approximation [11], [12]

$$B_{mn}(x, z) \sim -ik2^{5/4} \left(\frac{L_x}{8\pi k} \right)^{1/2} \times \exp\left\{i\left[k\left(\tilde{R}_{mn} + ib_n\right) + \pi/4\right]\right\} \frac{(z - \tilde{z}'_{mn})}{\tilde{R}_{mn}^{3/2}} \quad (10)$$

with \tilde{R}_{mn} representing the *complex distance*

$$\tilde{R}_{mn} = \overline{P_o \tilde{P}'_{mn}} = \sqrt{(x - \tilde{x}'_{mn})^2 + (z - \tilde{z}'_{mn})^2} \quad (11)$$

between the observer at $P_o = (x, z)$ and the *complex source point* (CSP), $\tilde{P}'_{mn} = (\tilde{x}'_{mn}, \tilde{z}'_{mn}) = (mL_x + ib_n \sin \theta_n, ib_n \cos \theta_n)$, where, in accord with the radiation condition [see (4)], the square root is defined by $\text{Re}(\tilde{R}_{mn}) \geq 0$. Here and henceforth, the tilde \sim denotes a complex quantity. The CSP displacement parameter (Fresnel length) b_n is related to the beam lattice period L_x and the beam axis angle $\theta_n = \sin^{-1}(n\lambda/L_x)$ via $b_n = (L_x \cos \theta_n)^2 / \lambda$ [11], and (10) is valid in the paraxial far-zone of each beam, $|\tilde{R}_{mn}| \gg b_n$. As the tilt index n increases to $|n| > L_x/\lambda$, the beam tilt angle θ_n becomes complex, and the corresponding beams become *evanescent*.

B. Narrow-Waisted Beams

As emphasized in [1], [11], and [12], *narrow-waisted* beams ($L_x \lesssim \lambda \ll d$) have several attractive features. First, the Gabor coefficients can be estimated with good approximation by *sampling* the aperture field distribution, avoiding the time-consuming integration (7) [1]

$$A_{mn} \approx \begin{cases} (L_x/\sqrt{2})^{1/2} F(mL_x), & n = 0 \\ 0, & n \neq 0 \end{cases} \quad (12)$$

so that

$$E_y(x, z) \approx \sum_{|m| \leq (d/2L_x)} A_{m0} B_{m0}(x, z) \quad (13)$$

$$B_{m0}(x, z) \sim -ik2^{5/4} \left(\frac{L_x}{8\pi k} \right)^{1/2} \times \exp\left\{i\left[k\left(\tilde{R}_{m0} + ib\right) + \pi/4\right]\right\} \frac{(z - ib)}{\tilde{R}_{m0}^{3/2}} \quad (14)$$

$$\tilde{R}_{m0} = \sqrt{(x - mL_x)^2 + (z - ib)^2} \quad (15)$$

$$b = b_0 = L_x^2/\lambda. \quad (16)$$

In this approximation, the tilted ($n \neq 0$) beams in the Gabor expansion, which generate evanescent “far fields” for $L_x/\lambda < |n|$, are ignored. Second, for narrow-waisted beams, the CSP paraxial *far-zone* approximation (10) can be invoked at *moderate* distance and, therefore, the paraxial beam superposition gives accurate results even in the *near zone* of the *aperture*. Third, as shown in [11]–[14], interaction of narrow-waisted beams with an environment can be effectively tracked by *complex ray asymptotics*.

C. Linearly Phased Aperture

As shown in [1] and [11], narrow-waisted beams work very well for nonphased apertures, but usually require finer aperture sampling in the presence of phasing. There are, however, special cases where more efficient implementations are possible. In particular, we consider a linearly phased aperture, which will efficiently parameterize the general case of nonlinear phasing later on

$$F(x) = g(x) \exp(ikx \sin \theta_A) \quad (17)$$

where $g(x)$ is a real function and θ_A denotes the real tilt angle of the main radiation lobe with respect to the z axis. In this case, a more effective discretization can be obtained by Gabor expanding the real function $g(x)$ only and including the linear phasing in the beam integral (9) for the B_{m0} beam propagator. Accordingly, the narrow-waisted ($L_x \lesssim \lambda \ll d$) beam expansion can be recast as (for simplicity, the subscript “ $m0$ ” is, henceforth, replaced by “ m ”)

$$E_y(x, z) \approx \sum_{|m| \leq (d/2L_x)} C_m \mathcal{B}_m(x, z) \quad (18)$$

where

$$C_m = \left(L_x/\sqrt{2} \right)^{1/2} g(mL_x), \quad |m| \leq (d/2L_x) \quad (19)$$

$$\mathcal{B}_m(x, z) = -ik2^{5/4} \left(\frac{L_x}{8\pi k} \right)^{1/2} \times \exp\left\{i\left[k\left(\tilde{R}_m + mL_x \sin \theta_A + ib\right) + \pi/4\right]\right\} \times \frac{(z - ib \cos \theta_A)}{\tilde{R}_m^{3/2}} \quad (20)$$

$$\tilde{R}_m = \sqrt{(x - mL_x - ib \sin \theta_A)^2 + (z - ib \cos \theta_A)^2} \quad (21)$$

$$b = (L_x \cos \theta_A)^2/\lambda. \quad (22)$$

The beam propagator (20) differs from B_{m0} in (14) by the phase shift ($ikmL_x \sin \theta_A$) and by the different definitions of

Fig. 3. Linearly phased cosine-tapered aperture distribution in (17), (23) ($d = 10\lambda$, $\theta_A = 30^\circ$) (see Fig. 1). Near-zone ($z = 5\lambda$) radiated field synthesized using narrow-waisted nontilted and tilted beams is compared with the reference solution [Kirchhoff integration in (2)]. — Reference solution; --- Tilted beam synthesis ($L_x = 0.02d$); Nontilted beam synthesis ($L_x = 0.02d$).

\tilde{R}_m and b in (21), (22), respectively, which produce the propagation-matched tilt θ_A in the beam direction (see Fig. 1). For comparison of the tilted and nontilted formulations, we consider the linearly phased distribution (17) with cosine tapering

$$g(x) = \begin{cases} \cos(\pi x/d), & |x| \leq d/2 \\ 0, & |x| > d/2 \end{cases} \quad (23)$$

$\theta_A = 30^\circ$, and a fixed beam lattice period ($L_x = 0.02d$). In Fig. 3, the near-zone fields synthesized under the same conditions with the same number of narrow-waisted nontilted (13) and tilted (18) beams are compared with the reference solution [brute force Kirchhoff integration in (2)]. The tilted beam synthesis is hardly distinguishable from the reference solution, whereas the nontilted synthesis is somewhat less accurate in magnitude.

III. TD FORMULATION

We shall now explore the extension of the FD results for aperture radiation in Section II to time-dependent excitation, in particular to short pulses. To this end, we consider a space-time aperture field distribution at $z = 0$

$$e_y(x, z = 0, t) = f(x, t), \quad |x| \leq d/2. \quad (24)$$

Using the 2D TD Green's function [18, Sec. 7.3]

$$g_{2D}(x, z, t; x', z' = 0, t') = \frac{H(t - t' - R/c)}{2\pi\sqrt{(t - t')^2 - (R/c)^2}} \quad (25)$$

with R defined in (4), c representing the speed of light, and $H(\cdot)$ representing the Heaviside step function, the field radiated into the half-space $z > 0$ can be expressed via the space-time Kirchhoff integration [18], [19]

$$\begin{aligned} e_y(x, z, t) &= \frac{z}{\pi} \int_{-d/2}^{d/2} dx' \frac{1}{R^2} \int_{-\infty}^{t-R/c} (t - t') \frac{\partial f}{\partial t'}(x', t') \\ &\quad \frac{dt'}{\sqrt{(t - t')^2 - (R/c)^2}} \end{aligned} \quad (26)$$

It is shown in Appendix A that the FD and TD fields $E_y(x, z, \omega)$ and $e_y(x, z, t)$ in (2) and (26), respectively, are related through the Fourier transform pair

$$\begin{aligned} e_y(x, z, t) &= \frac{1}{2\pi} \int_{-\infty}^{\infty} E_y(x, z, \omega) \exp(-i\omega t) d\omega \\ E_y(x, z, \omega) &= \int_{-\infty}^{\infty} e_y(x, z, t) \exp(i\omega t) dt. \end{aligned} \quad (27)$$

Direct numerical integration of (26) is complicated by the (integrable) square-root singularity at the upper limit $t' = t - R/c$ and requires care in its execution. Here, we use the Newton-Cotes scheme proposed in [19] for the numerical integration of (26), which represents our reference solution.

A. TD Beam Discretization: Linear-Delay Aperture Fields

The GB discretization for the time-harmonic aperture distribution in Section II can be generalized to arbitrary time-dependent excitation by use of a four-index Gabor series, which is set on a discretized lattice in the eight-dimensional (space-wavenumber, time-frequency) phase space (see [6] for analytic and computational issues). A condensed summary of the analytic results of section III-A has been given in [13], together with one simple numerical example. In our presentation below we give detailed derivations that were omitted in [13] but are required for complete understanding of the results. Moreover, we have here a much more comprehensive set of numerical examples as well as calibration of accuracy, which are not contained in [13]. The results in this section are used for the important generalization in Section III-B to nonlinear-delay profiles which is entirely new.

For assessment of the extent to which the FD narrow-waisted beam approach can be generalized to TD (short-pulse) excitation, we begin by considering the case of a space-time separable aperture field with linear time delay (assuming θ_A real)

$$f(x, t) = g(x)p(t - c^{-1}x \sin \theta_A) \quad (28)$$

and its FD counterpart via (27)

$$F(x, \omega) = P(\omega)g(x) \exp(ikx \sin \theta_A) \quad (29)$$

where $p(t)$ is a time-pulse with characteristic width T_p , and $P(\omega)$ is the Fourier transform of $p(t)$,

$$P(\omega) = \int_{-\infty}^{\infty} p(t) \exp(i\omega t) dt. \quad (30)$$

Equation (29) differs from (17) by the (spatially independent) frequency-dependent weight factor $P(\omega)$. This TD counterpart of the linearly phased aperture in Section II-C generates a space-time-resolved pulse propagating in the θ_A direction (see Fig. 1), with an assumed normalized pulse length much shorter than the aperture dimension d , i.e., $cT_p \ll d$.

Fourier inversion of the narrow-waisted tilted beam expansion (18) for a FD linearly phased aperture field yields a pulsed beam (PB) expansion for the corresponding TD aperture field in (28). However, the evanescent spectrum content in the FD beam propagator (20) motivates use of the *analytic signal* formulation

instead of the standard Fourier transform [5], [8]. The analytic signal $f^+(t)$ is defined via the one-sided Fourier transform

$$f^+(t) = \frac{1}{\pi} \int_0^\infty F(\omega) \exp(-i\omega t) d\omega, \quad \text{Im}(t) \leq 0 \quad (31)$$

where $F(\omega)$ is the conventional Fourier spectrum of the real signal $f(t)$ [see (27)]. The real signal for real t is recovered via

$$f(t) = \text{Re} \left[f^+(t) \right]. \quad (32)$$

The analytic TD counterpart of the narrow-waisted FD beam expansion (18) for the aperture field distribution (29) may thus be written as

$$e_y^+(x, z, t) \approx \sum_{|m| \leq (d/2L_x)} c_m b_m^+(x, z, t) \quad (33)$$

where the analytic PB propagator b_m^+ is given in terms of the paraxial, far-zone FD propagator \mathcal{B}_m in (20)

$$b_m^+(x, z, t) = \frac{1}{\pi} \int_0^\infty \mathcal{B}_m(x, z, \omega) P(\omega) \times \exp(-i\omega t) d\omega \quad \text{Im}(t) \leq 0. \quad (34)$$

For implementation, one can choose a frequency-independent beam lattice period L_x (resulting in a frequency (i.e., wavelength)-dependent beam parameter b [see (22)], or a frequency-independent beam parameter b (resulting in a frequency-dependent L_x). We consider frequency-independent L_x preferable because this yields frequency-independent Gabor coefficients [see (19)]. The real TD field e_y then follows from (33) and (34)

$$e_y(x, z, t) = \text{Re} \left[e_y^+(x, z, t) \right]$$

with

$$b_m(x, z, t) = \text{Re} \left[b_m^+(x, z, t) \right] \quad (35)$$

where the Gabor coefficients c_m can be estimated through aperture sampling when $L_x \lesssim \lambda \ll d$ [see (19)]

$$c_m = \left(L_x / \sqrt{2} \right)^{1/2} g(mL_x), \quad |m| \leq (d/2L_x). \quad (36)$$

For the important class of Gaussian time pulses, we have found useful closed-form approximations for the integral in (34). In particular, we use a Rayleigh (four-times-differentiated Gaussian) pulse (see Fig. 4)

$$p(t) = \exp \left[-\frac{50(t - T_p/2)^2}{T_p^2} \right] \times \left[1 + \frac{10000(t - T_p/2)^4 - 600(t - T_p/2)^2 T_p^2}{3T_p^4} \right] \quad (37)$$

with spectrum

$$P(\omega) = \sqrt{\frac{\pi}{2}} \frac{\omega^4 T_p^5}{150000} \exp \left(-\frac{\omega^2 T_p^2}{200} + i \frac{\omega T_p}{2} \right) \quad (38)$$

which has desirable wideband properties, being sufficiently bounded away from $\omega = 0$ and ∞ . However, the procedure below can be applied to any kind of modulated or differentiated Gaussian pulse.

The beam parameter b and hence, the complex distance \tilde{R}_m (21) in (20) are *frequency dependent* because the beam lattice period L_x has been chosen frequency independent. For $z \gg |b \cos \theta_A|$, the amplitude factor in the FD beam propagator (20) can be approximated by

$$\frac{(z - ib \cos \theta_A)}{\tilde{R}_m^{3/2}} \approx \frac{z}{R_m^{3/2}} \quad R_m = \sqrt{(x - mL_x)^2 + z^2} \quad (39)$$

where the distance $R_m \approx \tilde{R}_m$ is *real* and frequency independent. In the phase, under the same conditions, we retain the first order paraxial correction

$$\begin{aligned} \tilde{R}_m &\approx z_{bm} - ib + \frac{x_{bm}^2}{2(z_{bm} - ib)} \\ &\approx z_{bm} - ib + \frac{x_{bm}^2(z_{bm} + ib)}{2z_{bm}^2}, \quad b \ll z_{bm} \end{aligned} \quad (40)$$

where (x_{bm}, z_{bm}) are the beam coordinates (see Fig. 1)

$$\begin{bmatrix} x_{bm} \\ z_{bm} \end{bmatrix} = \begin{bmatrix} \cos \theta_A & -\sin \theta_A \\ \sin \theta_A & \cos \theta_A \end{bmatrix} \begin{bmatrix} x - mL_x \\ z \end{bmatrix}. \quad (41)$$

The phase approximation (40) is valid in the paraxial region of each beam

$$|z_{bm} - ib| \gg |x_{bm}| \quad (42)$$

together with the constraint that the beam parameter b remains small over the bandwidth Ω_p of the pulse spectrum $P(\omega)$

$$b = \frac{(L_x \cos \theta_A)^2 \omega}{2\pi c} \ll z_{bm}, \quad \omega \leq \Omega_p. \quad (43)$$

With these approximations, the integral in (34) can be evaluated in closed form, and the analytic PB propagator can be written explicitly as (see Appendix B for details)

$$\begin{aligned} b_m^+(x, z, t) &\approx \eta_m \left[\alpha_m \Gamma \left(\frac{11}{4} \right) M_1 \left(5 \sqrt{\frac{\pi}{2}} \frac{\beta_m}{\alpha_m} \right) \right. \\ &\quad \left. + 5 \sqrt{2\pi} i \beta_m \Gamma \left(\frac{13}{4} \right) M_2 \left(5 \sqrt{\frac{\pi}{2}} \frac{\beta_m}{\alpha_m} \right) \right] \end{aligned} \quad (44)$$

with

$$\alpha_m(x, z) = \sqrt{\pi(cT_p z_{bm})^2 + 50(L_x x_{bm} \cos \theta_A)^2} \quad (45)$$

$$\begin{aligned} \beta_m(x, z, t) &= x_{bm}^2 + z_{bm}(2z_{bm} + cT_p - 2ct) \\ &\quad + 2mL_x z_{bm} \sin \theta_A \end{aligned} \quad (46)$$

Fig. 4. Rayleigh pulse. (a) Temporal profile in (37). (b) Spectrum (magnitude) in (38).

$$\eta_m(x, z) = \frac{4z\sqrt{10L_x}\pi^{7/4}(cT_p)^5 z_{bm}^{11/2} \exp(-i\pi/4)}{3R_m^{3/2} \alpha_m(x, z)^{13/2}} \quad (47)$$

$$M_1(y) = {}_1F_1\left(\frac{11}{4}, \frac{1}{2}, -y^2\right) \quad (48)$$

$$M_2(y) = {}_1F_1\left(\frac{13}{4}, \frac{3}{2}, -y^2\right) \quad (49)$$

where R_m , x_{bm} and z_{bm} are defined in (39) and (41), $\Gamma(\cdot)$ is the gamma function [20, Sec. 6], and ${}_1F_1(u, v, y)$ is the Kummer confluent hypergeometric function [20, Sec. 13]. Since modulation or differentiation operations affect only the arguments of ${}_1F_1(u, v, y)$, the above reduction can be applied to any Gaussian-envelope pulse.

The following simple approximations can be exploited for the functions M_1 and M_2 (see Appendix C):

$$M_1(y) \approx \exp(-y^2) \left(1 - \frac{9}{2}y^2 + \frac{15}{8}y^4 - \frac{y^6}{16} - \frac{3}{896}y^8 - \frac{y^{10}}{3840} \right) \quad (50)$$

$$M_2(y) \approx \exp(-y^2) \left(1 - \frac{7}{6}y^2 + \frac{7}{40}y^4 + \frac{y^6}{240} + \frac{y^8}{3456} + \frac{y^{10}}{42240} \right). \quad (51)$$

Fig. 5 shows comparisons between the exact functions (computed via reliable numerical routines [21]) and the proposed approximations (50), (51). The results essentially overlap on the scale of the plots. Since the functions $M_{1,2}$ resemble the form and shape of the Rayleigh pulse in (37) and Fig. 4, then using (50) and (51), the TD beam propagator (44) can be computed very efficiently. Fig. 6 shows a number of instantaneous snapshots of $b_m(x, z, t)$. Note the rapid transverse spatial spreading of the ray-like narrow-waisted PB, but its retention of the wave-front behavior in the longitudinal (radial) direction.

B. TD Beam Discretization: Nonlinear-Delay Aperture Fields

Extension of the TD Gabor algorithm in Section III-A to nonlinear delay profiles is an important new generalization. Instead

Fig. 5. Comparison between the exact and approximated functions $M_{1,2}$ in (48)–(51). — Exact; - - - Approximated.

Fig. 6. Instantaneous snapshots of the TD beam propagator $b_m(x, z, t)$ ($m = 0$, $L_x = d/20$, $\theta_A = 0$, $cT_p = 0.5$). (a) $ct = 1$. (b) $ct = 2$. (c) $ct = 3$. (d) $ct = 4$.

of the linear delay in (28), we now consider the aperture field distribution

$$f(x, t) = h(x)p(t - c^{-1}\phi(x)) \quad (52)$$

with its FD counterpart

$$F(x, \omega) = P(\omega)h(x) \exp\left[i\frac{\omega}{c}\phi(x)\right] \quad (53)$$

where $h(x)$ and $\phi(x)$ are real functions. Recalling the efficient treatment of the linear delay fields in Section III-A, we split the phase (delay) function $\phi(x)$ into a linear part plus a nonlinear remainder

$$\phi(x) = x \sin \theta_A + \phi_{NL}(x) \quad (54)$$

where $\phi_{NL}(x)$ does not contain linear terms. The FD narrow-waisted tilted beam decomposition (18) of Section II-C can, thus, be applied, with $g(x)$ in (17) given by

$$g(x) = h(x) \exp[ik\phi_{NL}(x)]. \quad (55)$$

The corresponding FD Gabor coefficients [see (19)] are complex

$$C_m = \left(L_x / \sqrt{2} \right)^{1/2} h(mL_x) \exp[ik\phi_{NL}(mL_x)] \quad (56)$$

$$|m| \leq (d/2L_x)$$

and the corresponding TD beam expansion differs only slightly from (33)

$$e_y(x, z, t) \approx \sum_{|m| \leq (d/2L_x)} h_m b_m(x, z, t - \tau_m) \quad (57)$$

where b_m is the real part of the analytic PB propagator in (44), and

$$h_m = \left(L_x / \sqrt{2} \right)^{1/2} h(mL_x)$$

$$\tau_m = c^{-1} \phi_{NL}(mL_x), \quad |m| \leq (d/2L_x). \quad (58)$$

C. Assessment of Accuracy

The explicit analytic results in (44) are based on the approximations (39) and (40), which are valid in the paraxial *far-zone* (42). An additional condition is the *smallness* of the beam parameter b over the whole bandwidth of interest [see (43)]. This latter restriction, in turn, determines the maximum allowable lattice period (i.e., the minimum number of beams) for specified Ω_p , θ_A and observation point. A rough theoretical estimate can be obtained from (43). For specified observation plane at $z = z_{obs}$ and recalling that $z_{bm} = z_{obs} / \cos \theta_A$ (see Fig. 1) the overall constraint can be expressed by the following inequality in terms of the nondimensional estimator Q

$$Q \equiv N_b^{-1} \sqrt{\frac{\kappa(\cos \theta_A)^3}{\chi}} \ll 1 \quad (59)$$

where the integer $N_b = d/L_x$ represents the number of beams in the expansion (33), $\kappa = \Omega_p T_p / 2\pi$ is the normalized bandwidth of the pulse $p(t)$, and $\chi = z_{obs} / F_d$ is the distance to the observation plane scaled by the Fresnel distance of the aperture, $F_d = d^2 / (cT_p)$. The nondimensional estimator $Q \ll 1$ contains all relevant parameters of the problem. For example, decreasing the number of beams N_b can be compensated by a corresponding increase of $(z_{obs})^{1/2}$. However, a finer discretization may be required in the presence of nonlinear phasing/delay for the same degree of accuracy.

D. Numerical Results

The TD narrow-waisted beam expansions in (35), (57) have been calibrated against a reference solution implemented by space-time Kirchhoff integration of (26) in an extensive number of numerical simulations. We present and discuss selected typical results, starting with the linear-delay space-time aperture distribution (28) where $g(x)$ is the cosine tapering in (23) and $p(t)$ is the time dependence of the Rayleigh pulse in (37). Figs. 7 and 8 show typical results for the nonphased case ($\theta_A = 0$). Specifically, Fig. 7(a) depicts the time evolution of the y -directed scalar electric field at a fixed observation point in the

Fig. 7. Radiated field due to nonphased ($\theta_A = 0$) cosine-tapered aperture distribution. Parameters: $cT_p = 0.5$, $d = 5 = 10cT_p$ (arbitrary units). Reference solution via space-time Kirchhoff integration of (26): solid curves. TD narrow-waisted beam synthesis in (35): dashed and dotted curves. Observation points for the temporal profile are on the beam axis ($x = 0$). (a) Temporal profile at $x = 0$, $z = 5 = 0.1F_d$ (arbitrary units); (b) Spatial transverse profile at $z = 5$, $ct = 5.25$; --- 5 beams ($Q = 1.6$, $\Delta e_y = -2$ dB); 10 beams ($Q = 0.8$, $\Delta e_y = -14$ dB), - - - - 30 beams ($Q = 0.26$, $\Delta e_y = -31$ dB). The r.m.s. errors Δe_y pertain to Fig. 7(a).

Fig. 8. Parameters as in Fig. 7. (a) Temporal profile at $x = 0$, $z = 20 = 0.4F_d$, 15 beams ($Q = 0.27$, $\Delta e_y = -32$ dB). (b) Spatial transverse profile at $z = 20$, $ct = 20.25$, 15 beams ($Q = 0.27$). (c) Temporal profile at $x = 0$, $z = 50 = F_d$, 10 beams ($Q = 0.25$, $\Delta e_y = -34$ dB). (d) Spatial transverse profile at $z = 50$, $ct = 50.25$, 10 beams ($Q = 0.25$). Reference solutions (solid curves) and beam solutions (dashed curves) coincide on the scale of the plots.

near zone ($z = 0.1F_d$) of a large aperture ($d = 10cT_p$); the reference space-time Kirchhoff integration (26) is compared with the TD beam synthesis (35) for various numbers of beams. In all simulations, we used a pulse-bandwidth value $\Omega_p T_p = 40$ (see

Fig. 9. Radiated field due to linearly phased ($\theta_A = 30^\circ$) cosine-tapered aperture distribution. Parameters: $cT_p = 0.5$, $d = 5 = 10cT_p$ (arbitrary units). Observation points for the temporal profiles are on the tilted beam axis θ_A . (a) Temporal profile at $x = 2.89$, $z = 5 = 0.1F_d$ (arbitrary units), 25 beams ($Q = 0.26$, $\Delta e_y = -32$ dB). (b) Spatial transverse profile at $z = 5$, $ct = 6.05$, 25 beams ($Q = 0.26$). (c) Temporal profile at $x = 11.5$, $z = 20 = 0.4F_d$, 12 beams ($Q = 0.27$, $\Delta e_y = -33$ dB). (d) Spatial transverse profile at $z = 20$, $ct = 23.3$, 12 beams ($Q = 0.27$). (e) Temporal profile at $x = 28.9$, $z = 50 = F_d$, 8 beams ($Q = 0.25$, $\Delta e_y = -33$ dB). (f) Spatial transverse profile at $z = 50$, $ct = 58$, 8 beams ($Q = 0.25$). Reference solutions (solid curves) and beam solutions (dashed curves) coincide on the scale of the plots.

Fig. 4), which sets the reference level for the nondimensional estimator Q in (59). As expected, the agreement improves with increase in the number of beams, and satisfactory accuracy is achieved for $Q \leq 0.3$. In order to better quantify the accuracy of the TD beam synthesis and the role of the nondimensional estimator Q , we computed the r.m.s. (energy) error at a fixed observation point

$$\Delta e_y := \frac{\int_{-\infty}^{\infty} |e_y^{(\text{ref})}(x, z, t) - e_y^{(\text{beam})}(x, z, t)|^2 dt}{\left[\int_{-\infty}^{\infty} |e_y^{(\text{ref})}(x, z, t)|^2 dt \int_{-\infty}^{\infty} |e_y^{(\text{beam})}(x, z, t)|^2 dt \right]^{1/2}} \quad (60)$$

whose values are explicitly indicated in the figure captions. It is observed that values of $Q \leq 0.3$ yield errors $\lesssim -30$ dB. We shall use Q as a convenient calibrator of the accuracy in the numerical experiments. It is observed from the transverse cut shown in Fig. 7(b) that despite the use of the paraxial far-zone approximation (42), the TD beam synthesis works quite well even in the near zone of the aperture ($z = 0.1F_d$) and not only around the main radiation lobe. As the observation distance increases, a coarser discretization can be used subject to (59). For

Fig. 10. Radiated field due to cosine-tapered focused aperture distribution in (61), computed via space-time Kirchhoff integration of (26). Parameters: $cT_p = 0.5$, $d = 5 = 10cT_p$, $L_f = 10 = 0.2F_d$ (arbitrary units). Instantaneous snapshots at various times. (a) $ct = 3.25$; (c) $ct = 10.235$; (e) $ct = 30.22$. (b), (d), (f) Gray-scale plots corresponding to (a), (c), (e), respectively. See also the spatial profiles in Figs. 12(b), 11(b) and 12(d) for different visualization.

instance, Fig. 8(a) and (b) show results for a moderate observation distance ($z = 0.4F_d$), whereas Fig. 8(c) and (d) show far-zone ($z = F_d$) results. In these examples, only one beam synthesis is shown, with the beam lattice period chosen so as to assure $Q \leq 0.3$, according to the above calibration; accuracy is confirmed. We conclude that even at moderate distances, acceptable results can be obtained with a relatively small number of beams (~ 20). The corresponding data for a linear-delay example ($\theta_A = 30^\circ$) are shown in Fig. 9. The same conclusions apply, except that the field maxima are tracked along the tilted beam axis θ_A .

As our final and most important example, we consider a nonlinearly phased aperture distribution. In particular, we have chosen a cosine-tapered aperture field with quadratic delay

$$f(x, t) = \begin{cases} \cos(\pi x/d)p[t + x^2/(2cL_f)], & |x| \leq d/2 \\ 0, & |x| > d/2 \end{cases} \quad (61)$$

which represents the TD counterpart of a typical time-harmonic focusing ($L_f > 0$) or defocusing ($L_f < 0$) distribution, with L_f representing the conventional focal length. The focusing case is the most challenging, since standard (nonuniform) ray asymptotics would fail due to the presence of caustic transition regions. Moreover, we have chosen numerical values so as to get focusing at moderate distance from the aperture ($L_f = 0.2F_d$). A

Fig. 11. Radiated field due to cosine-tapered focused aperture distribution in (61), observed in the focal plane. Parameters: $cT_p = 0.5$, $d = 5 = 10cT_p$, $L_f = 10 = 0.2F_d$ (arbitrary units). Reference solution via space-time Kirchhoff integration of (26): solid curves. TD narrow-waisted beam synthesis in (57): dashed and dotted curves. (a) Temporal profile at $x = 0$, $z = 10 = L_f = 0.2F_d$. (b) Spatial transverse profile at $z = 10$, $ct = 10.235$; --- 10 beams ($Q = 0.56$, $\Delta e_y = -9$ dB), 30 beams ($Q = 0.19$, $\Delta e_y = -25$ dB), - - - - 60 beams ($Q = 0.09$, $\Delta e_y = -33$ dB). The r.m.s. errors Δe_y pertain to Fig. 11(a).

sequence of instantaneous snapshots of the radiated field at different times, computed via the space-time Kirchhoff integration in (26), is shown in Fig. 10. One observes how the space-time wavepacket, starting from the initial distribution (61), has a concave (focusing) wavefront on its way to the focal plane, i.e., for $z < L_f$ [Fig. 10(a) and (b)]; it experiences its maximum space-time localization at the focal plane $z = L_f$ [Fig. 10(c) and (d)], and spreads out beyond the focal plane with a convex wavefront [Fig. 10(e) and (f)]. In order to assess the accuracy of the PB expansion in (57), the comparison with the reference solution is shown in Figs. 11 and 12 for representative temporal and spatial cuts at various observation distances. Fig. 11(a) and (b) show the convergence results at the focal plane $z = L_f$ (most challenging test). A slightly finer discretization is needed than in the linear-delay case, for the same degree of accuracy; accurate syntheses ($\Delta e_y < -30$ dB) are obtained for $Q \leq 0.1$, but reasonable accuracy ($\Delta e_y < -20$ dB) is still within the less stringent $Q \leq 0.3$ range. Fig. 12(a)–(d), show results for observation distances smaller ($z = 0.3L_f$) and larger ($z = 3L_f$) than the focal length, with the number of beams chosen so as to assure $Q \leq 0.1$. The spatial profiles in Fig. 12(b) and (d) show the broader spatial extent of the wavefront, with respect to the focal plane pattern in Fig. 11(b), which is analogous to the snapshots in Fig. 10(a) and (e). The temporal profile of the incident pulse in Fig. 12(a) is distorted at [Fig. 11(a)] and beyond [Fig. 12(c)] the focus due to caustic-induced phase shifts.

Fig. 12. Parameters as in Fig. 11, observed before and beyond the focal plane. (a) Temporal profile at $x = 0$, $z = 3 = 0.3L_f = 0.06F_d$, 100 beams ($Q = 0.1$, $\Delta e_y = -33$ dB); (b) Spatial transverse profile at $z = 3$, $ct = 3.25$, 100 beams ($Q = 0.1$); (c) Temporal profile at $x = 0$, $z = 30 = 3L_f = 0.6F_d$, 30 beams ($Q = 0.1$, $\Delta e_y = -37$ dB); (d) Spatial transverse profile at $z = 30$, $ct = 30.22$, 30 beams ($Q = 0.1$). Reference solutions (solid curves) and beam solutions (dashed curves) coincide on the scale of the plots.

IV. CONCLUSION

By extending the time-harmonic approach presented in [1], a 2D narrow-waisted pulsed beam algorithm has been presented which allows an effective discretization of short-pulse radiation from one-dimensional (1-D) large apertures. Analytic approximations in the form of readily computable functions have been obtained for aperture field distributions with separable space-time dependence, general phasing, and Gaussian pulse excitation.

Accuracy assessments of the beam algorithm have been formalized theoretically in terms of the nondimensional estimator Q , and calibrated numerically through a variety of simulations involving phased and focused pulsed aperture field profiles; independent calibration of the numerical data was achieved by comparison with a rigorously based brute force space-time Kirchhoff integration. The results are encouraging and confirm that within the stated criteria, one can make fairly reliable predictions of performance.

Overall, it appears that reasonably accurate syntheses can be obtained with a moderate number of beams, within the constraint $Q \leq 0.3$, thus making the algorithm a promising efficient parameterizer for beam tracing in the presence of propagation and scattering environments. Toward this goal, the TD extension of the previously performed FD studies in [11]–[14] is now under consideration [22]. For extension to two-dimensional (2-D) apertures which generate three-dimensional (3-D) (vector) fields, see [23].

APPENDIX A PERTAINING TO (26)

By Fourier transforming the FD radiated field in (2), recalling that G_{2D} and g_{2D} are related through the Fourier transform pair

(27) [18], and applying the convolution theorem [24], the TD field radiated into the $z > 0$ halfspace can be written as

$$e_y(x, z, t) = -\frac{1}{\pi} \int_{-d/2}^{d/2} dx' \frac{\partial}{\partial z} \int_{-\infty}^{t-R/c} \frac{f(x', t')}{\sqrt{(t-t')^2 - (R/c)^2}} dt' \quad (62)$$

with R being defined in (4), and with $f(x, t)$ and $F(x, \omega)$ being related through the Fourier transform pair (27). The differentiation of the temporal integral in (62) can be performed through differentiation under the integral sign, coupled with a limiting procedure to circumvent the singularity at the upper integration limit (see [19] for details), yielding

$$\begin{aligned} \frac{\partial}{\partial z} \int_{-\infty}^{t-R/c} \frac{f(x', t')}{\sqrt{(t-t')^2 - (R/c)^2}} dt' \\ = -\frac{z}{R^2} \int_{-\infty}^{t-R/c} \frac{(t-t')}{\sqrt{(t-t')^2 - (R/c)^2}} \frac{\partial f}{\partial t'}(x', t') dt' \end{aligned} \quad (63)$$

from which (26) follows.

APPENDIX B PERTAINING TO (44)

By substituting (20) and (38), with (22), (39), (40), into (34) one obtains

$$\begin{aligned} b_m^+(x, z, t) = -\frac{2^{-3/4} e^{i3\pi/4} \sqrt{L_x} z T_P^5}{150000\pi \sqrt{c} R_m^{3/2}} \int_0^\infty \omega^{9/2} \\ \times \exp \left[i\omega \left(\frac{i\alpha_m^2 \omega + 100\pi c z_{bm} \beta_m}{200c^2 \pi z_{bm}^2} \right) \right] d\omega \end{aligned} \quad (64)$$

with α_m, β_m defined in (45), (46), respectively. The frequency integral in (64), in its canonical form

$$I(\xi, \zeta) = \int_0^\infty \omega^{9/2} \exp(i\xi\omega - \zeta\omega^2) d\omega, \quad \zeta > 0 \quad (65)$$

can be evaluated in closed form (we used Mathematica [21]) as

$$\begin{aligned} I(\xi, \zeta) = \frac{\zeta^{-13/4}}{2} \left[\sqrt{\zeta} \Gamma \left(\frac{11}{4} \right) {}_1F_1 \left(\frac{11}{4}, \frac{1}{2}, -\frac{\xi^2}{4\zeta} \right) \right. \\ \left. + i\xi \Gamma \left(\frac{13}{4} \right) {}_1F_1 \left(\frac{13}{4}, \frac{3}{2}, -\frac{\xi^2}{4\zeta} \right) \right] \end{aligned} \quad (66)$$

where $\Gamma(\cdot)$ is the gamma function [20, Sec. 6], and ${}_1F_1(u, v, y)$ is the Kummer confluent hypergeometric function [20, Sec. 13]. Equation (44) follows from (64), (66) after straightforward algebra.

APPENDIX C PERTAINING TO (50), (51)

The Kummer confluent hypergeometric function is defined as [20, Sec. 13]

$${}_1F_1(u, v, y) = \sum_{n=0}^{\infty} \frac{(u)_n y^n}{(v)_n n!} \quad (67)$$

where $(u)_n$ is the Pochhammer symbol [20]

$$(u)_n = u(u+1)(u+2)\cdots(u+n-1) \quad (u)_0 = 1. \quad (68)$$

A rapidly convergent approximation for the functions M_1 and M_2 in (48), (49) can be obtained by exploiting the Kummer transformation [20]

$${}_1F_1(u, v, y) = \exp(y) {}_1F_1(v-u, v, -y). \quad (69)$$

Accordingly

$$\begin{aligned} M_1(y) &= {}_1F_1 \left(\frac{11}{4}, \frac{1}{2}, -y^2 \right) \\ &= \exp(-y^2) {}_1F_1 \left(-\frac{9}{4}, \frac{1}{2}, y^2 \right) \\ &= \exp(-y^2) \left(1 - \frac{9}{2} y^2 + \frac{15}{8} y^4 - \frac{y^6}{16} - \frac{3}{896} y^8 \right. \\ &\quad \left. - \frac{y^{10}}{3840} + \mathcal{O}(y^{12}) \right) \end{aligned} \quad (70)$$

$$\begin{aligned} M_2(y) &= {}_1F_1 \left(\frac{13}{4}, \frac{3}{2}, -y^2 \right) \\ &= \exp(-y^2) {}_1F_1 \left(-\frac{7}{4}, \frac{3}{2}, y^2 \right) \\ &= \exp(-y^2) \left(1 - \frac{7}{6} y^2 + \frac{7}{40} y^4 + \frac{y^6}{240} + \frac{y^8}{3456} \right. \\ &\quad \left. + \frac{y^{10}}{42240} + \mathcal{O}(y^{12}) \right) \end{aligned} \quad (71)$$

as shown in (50) and (51).

Vincenzo Galdi (M'98)

He received the Laurea degree (*summa cum laude*) in electrical engineering and the Ph.D. degree in applied electromagnetics from the University of Salerno, Italy, in 1995 and 1999, respectively.

From April to December 1997, he held a Visiting Position in the Radio Frequency Division of the European Space Research & Technology Centre (ESTEC-ESA), Noordwijk, The Netherlands, where he was involved in developing CAD tools for microwave filters and phased-array antennas with coaxial excitation. In

September 1999, he received a European Union postdoctoral fellowship through the University of Sannio, Benevento, Italy. In October 1999, he became a Research Associate in the Department of Electrical and Computer Engineering, Boston University, Boston, MA, where he is currently working on wave-oriented imaging algorithms for landmine detection and classification. His research interests include analytical and numerical techniques for wave propagation in complex environments, path integrals, and stochastic resonance.

Dr. Galdi is the recipient of the 2001 International Union of Radio Science (URSI) "Young Scientist Award." He is a member of Sigma Xi.

Leopold B. Felsen (S'47–M'54–SM'55–F'62–LF'90) was born in Munich, Germany, on May 7, 1924. He received the B.E.E., M.E.E., and D.E.E. degrees from the Polytechnic Institute of Brooklyn, Brooklyn, NY, in 1948, 1950, and, 1952, respectively.

He emigrated to the United States in 1939 and served in the U.S. Army from 1943 to 1946. After 1952, he remained with the Polytechnic Institute of Brooklyn (now Polytechnic University), becoming a Professor in 1962 and University Professor in 1978. From 1974 to 1978, he was Dean of Engineering.

In 1994, he resigned from the full-time Polytechnic Faculty and became University Professor Emeritus. He is now a part-time Professor of Aerospace and Mechanical Engineering and Professor of Electrical and Computer Engineering at Boston University, Boston, MA. He is the author or coauthor of more than 300 papers and several books, including *Radiation and Scattering of Waves* (Englewood Cliffs, NJ: Prentice-Hall, 1973; Piscataway, NJ: IEEE Press, 1994). He is an Associate Editor of several professional journals and an editor of the *Wave Phenomena Series* (New York: Springer-Verlag). His research interests encompass wave propagation and diffraction in complex environments and in various disciplines, high-frequency asymptotic and short-pulse techniques, and phase-space methods with an emphasis on wave-oriented data processing and imaging.

Dr. Felsen is a member of Sigma Xi and a Fellow of the Optical Society of America and the Acoustical Society of America. He has held named Visiting Professorships and Fellowships at universities in the United States and abroad, including the Guggenheim in 1973 and the Humboldt Foundation Senior Scientist Award in 1981. In 1974, he was an IEEE Antennas and Propagation Society (APS) Distinguished Lecturer. He received the Balthasar van der Pol Gold Medal from the International Union of Radio Science (URSI) in 1975, an honorary doctorate from the Technical University of Denmark in 1979, the IEEE Heinrich Hertz Gold Medal for 1991, the APS Distinguished Achievement Award for 1998, the IEEE Third Millennium Medal in 2000 (nomination by APS), three Distinguished Faculty Alumnus Awards from Polytechnic University, and an IEEE Centennial Medal in 1984. He also has received Best Paper awards for several papers in which he was an author or coauthor. In 1977, he was elected to the National Academy of Engineering. He served on the APS Administrative Committee from 1963 to 1966 and as Vice Chairman and Chairman for both the United States (1966–1973) and the International (1978–1984) URSI Commission B.

David A. Castañón (S'68–M'79–SM'98) received the B.S. degree in electrical engineering from Tulane University, New Orleans, LA, in 1971 and the Ph.D. degree in applied mathematics from the Massachusetts Institute of Technology (MIT), Cambridge, in 1976.

From 1976 to 1981, he was a Research Associate with the Laboratory for Information and Decision Systems, MIT. From 1982 to 1990, he was Senior and Chief Research Scientist at Alphatech, Inc., Burlington, MA. Since 1990, he has been a Professor in the Department of Electrical and Computer Engineering, Boston University, Boston, MA. His research interests include stochastic control and estimation, optimization, and image processing.

Dr. Castañón served as a member of the Board of Governors of the IEEE Control Systems Society. He is also a member of AMS, SIAM, and INFORMS.

Moderately Rough Dielectric Interface Profile Reconstruction via Short-Pulse Quasi-Ray Gaussian Beams

Abstract

A new technique for estimating the coarse-scale profile of a moderately rough interface between air and a homogeneous dielectric half-space is presented. The proposed approach is based on space-time sparsely sampled reflected field observations and uses a quasi-ray Gaussian beam fast forward model, coupled with a compact parameterization of the surface profile in terms of B-splines, from which the profile estimation problem is posed as a nonlinear optimization problem. Numerical experiments are presented to assess accuracy, reliability and computational efficiency. The proposed approach finds application in adaptive schemes for rough surface underground imaging of shallowly buried targets via ultra-wideband ground penetrating radars.

Keywords

GPR, imaging, rough surfaces, Gaussian beams, short pulses.

I. INTRODUCTION

In ground penetrating radar (GPR) applications, the twice-traversed unknown rough interface separating air and soil acts as a major source of clutter by distorting the interrogating signal on its way to and from the targets of interest, and by generating complicated backscattered field patterns which may obscure the useful signals. Physics-based modeling of such clutter, which could significantly enhance the ultimate GPR performance, poses challenging problems from both the electromagnetic (EM) and signal processing viewpoints. Standard statistical approaches, which tend to model such distortion as additive colored Gaussian noise, perform reasonably well in *detection* problems [1], [2]. However, they have been found to yield limited accuracy and reliability in underground imaging techniques for target *localization* and *classification* (see, e.g., [3]), for which alternative approaches need to be explored. In this connection, we have been investigating a novel *adaptive* framework, based on *quasi-deterministic* compensation of the coarse-scale roughness effect. This approach is based on *prior* estimation of the coarse-scale roughness profile, which is accomplished by exploiting sparse reflected field observation data and fast forward scattering models. In this communication, we address this problem for the case of short-pulse illumination, typical of current ultra-wideband (UWB) GPR systems. The proposed approach is built on recently developed Gabor-based narrow-waisted *quasi-ray* Gaussian beam (GB) algorithms for short-pulse scattering from moderately rough dielectric interfaces [4]. By exploiting these fast forward models and a low-dimensional spline

interface parameterization, together with the (usually small) separation between the rough interface and the target, the prior surface estimation is posed as a nonlinear optimization problem by fitting the model-based prediction to the available *early-time* observation data. The subsequent problem of quasi-deterministic compensation and underground imaging via *late-time* response processing is addressed in a separate paper [5], with particular reference to shallowly buried plastic mine-like targets.

II. STATEMENT OF THE PROBLEM

We consider the two-dimensional (2D) problem geometry sketched in the (x, z) coordinate space of Fig. 1, where all quantities and fields are assumed to be y -independent. A homogeneous dielectric half-space (soil) of *known* relative permittivity ϵ_{r1} and conductivity σ_1 , bounded by a moderately rough interface with profile $z = h(x)$, is illuminated by a y -directed (TM-polarized) pulsed well-collimated electromagnetic (EM) field, generated by a large truncated aperture field distribution of width d at $z = z_A$, which is assumed to be well approximated by a pulsed truncated tapered plane wave,

$$e^i(\mathbf{r}, t) \sim g(x_B)p(t - c^{-1}z_B), \quad (1)$$

where $\mathbf{r} \equiv (x, z)$, c is the free-space wavespeed, $p(t)$ is a short pulse of length $T \ll d/c$, and (x_B, z_B) are beam centered coordinates,

$$\begin{bmatrix} x_B \\ z_B \end{bmatrix} = \begin{bmatrix} \cos \theta_A & \sin \theta_A \\ \sin \theta_A & -\cos \theta_A \end{bmatrix} \begin{bmatrix} x - x_A \\ z - z_A \end{bmatrix}. \quad (2)$$

In (1) and (2), $g(x_B)$ is a spatial taper, while θ_A and x_A denote the tilt angle of the radiated beam relative to the z -axis and its spatial displacement, respectively; parameters are chosen so that the illumination tapers to zero for $|x| \leq d/2$ and vanishes for $|x| > d/2$ (Fig. 1). At this stage of investigation, we ignore the presence of buried targets, which is dealt with elsewhere [5]. Furthermore, we also neglect the *noisy* (incoherent) contribution of finer-scale roughness, and focus on estimating the coarse scale roughness profile $h(x)$ from sparse reflected field observations. In [6], we addressed this problem for narrow-band stepped-frequency sparse observations. This approach is extended here to *pulsed* excitation. To proceed, the y -directed reflected electric field is sampled at N_t time instants

at N_r fixed receiver locations $x_1^r, \dots, x_{N_r}^r$ at the observation plane $z = z^r$; the *known term* in the problem is given by the set of $N_r \times N_t$ samples. In our numerical experiments in Sec. V, we shall use synthetic field observation data generated via a full-wave solution of the forward scattering problem (see [4] for details).

III. ROUGH SURFACE FORWARD SCATTERING MODEL

The forward scattering model, detailed in [4], is based on the Kirchhoff Physical Optics (PO) approximation in conjunction with the Gabor-based narrow-waisted pulsed beam (PB) discretization of 1D aperture field distributions in [7], and is restricted to moderate roughness (both in height and slope) and slightly lossy soils.

The PO “equivalent current”, which generates the reflected field, is first parameterized in the frequency domain in terms of x -domain discretized m -indexed Gabor basis functions with narrow width L , centered on the Gabor lattice points $x_m = mL$; these initial conditions generate narrow-waisted, quasi-ray, complex-source-point GBs propagating along the local reflection directions. For Rayleigh (i.e., differentiated Gaussian) pulses, the resulting time-domain analytic Fourier inversion integral can be approximated by rapidly computable closed form expressions, yielding the following approximate PO-PB expansion for the reflected field e^r (see [4] for details),

$$e^r(\mathbf{r}, t) \sim \sum_{|m| \leq (d/2L)} c_m^r b_m^r(\mathbf{r}, t - t_m), \quad (3)$$

where the Gabor expansion coefficients c_m^r and the time delays t_m are approximated by sampling the PO equivalent currents at the lattice points $x_m = mL$, and the PB propagators b_m^r are expressed in terms of rapidly computable confluent hypergeometric functions [4, Sec. IV-B]. The approximate forward scattering model in (3) has been validated and calibrated against a rigorous reference solution [4, Sec. V-A], and has been found to provide accurate and robust predictions for moderate roughness (both in height and slope), non-grazing incidence, and slightly lossy soils (see [4, Sec. V-C] for details). Numerical convergence is usually achieved with $d/L \sim 30$ to 100 (narrow-waisted) PBs, resulting in minimal storage requirements and typical computing times of 2 ms per space-time field sample on a 700 MHz PC. Moreover, for computing a number of field time samples at

fixed receiver locations, as required in Sec. IV, one can take advantage of the structure of the PB propagators in (3) (see [4, Sec. IV-B] for details) to compute the time-independent parts only once, with resulting typical computing times of 20 ms for a *whole* 100-sample waveform, as compared with about 240 secs. required by our full-wave reference solution. This light computational burden, is essential for the overall computational feasibility of the proposed surface estimation approach.

IV. SURFACE PROFILE ESTIMATION

Due to the inherent ill-posedness of the surface estimation problem, it is necessary to exploit *regularization* strategies. Acknowledging the implicit limits of retrievable information through inverse scattering, our regularization strategy is based on a compact parameterization of the unknown profile function in a suitable finite-dimensional space. As in [6], we model the surface profile $h(x)$ using a quartic B-spline parameterization [8] with fixed resolution matched to the coarse level of detail for the reconstruction,

$$h(x) = \sum_{n=-4}^{N_h-1} h_n s^{(4)}(x - x_{min} + n\Delta_x), \quad x_{min} \leq x \leq x_{max}, \quad (4)$$

whereby the coefficients $\{h_n\}$ become the *unknowns* of the problem. In (4), $s^{(4)}(\cdot)$ is a standard quartic B-spline basis function [8] (see also [6, Eq. (5)]) with finite spatial support $5\Delta_x$, where $\Delta_x = (x_{max} - x_{min})/N_h$ denotes a scale parameter whose choice can be guided by possible prior information and refined *adaptively* (see Sec. V). To prevent ill-conditioning, it is crucial that the number of unknown parameters to be retrieved does not substantially exceed the *essential* dimension of the observation data set. For the problem of interest in this paper, however, the intrinsic limitation in the retrievable information does not pose serious *quantitative* restrictions, since our implementation allows the number of unknowns to be kept fairly small ($N_h \lesssim 30$). By exploiting our PO-PB fast forward model in [4] and the spline interface profile parameterization in (4), the well-posedness of the problem is restored by estimating the unknown parameters via *fitting* the model-based forward scattering prediction to the available observation data, i.e., minimizing a suitable *cost functional*. We use a simple least square formulation,

$$J(\underline{h}) = \|\underline{\mathbf{e}}^r(\underline{h}) - \hat{\underline{\mathbf{e}}}^r\|^2 = \sum_{p=1}^{N_r} \sum_{q=1}^{N_t} \gamma_p \left(e_{pq}^r - \hat{e}_{pq}^r \right)^2, \quad (5)$$

where $\hat{e}_{pq}^r = \hat{e}^r(\mathbf{r}_p^r, t_{pq})$ denotes the y -directed reflected field *observed* at time $t_{pq} \in [T_p^{(on)}, T_p^{(off)}]$ at receiver locations $\mathbf{r}_p^r \equiv (x_p^r, z^r)$ (Fig. 1), $e_{pq}^r = e^r(\mathbf{r}_p^r, t_{pq}; \underline{h})$ denotes the corresponding *forward prediction* for the surface profile coefficients $\underline{h} = \{h_{-4}, \dots, h_{N_h-1}\}$, and γ_p are normalization coefficients. Anticipating the possible presence of buried targets, dealt with in [5], the observation intervals $[T_p^{(on)}, T_p^{(off)}]$ are chosen so as to gate out the *late-time* response (i.e., causal contributions from regions beyond a critical depth), in order to prevent any possible bias in the surface profile estimation.

In general, the predictive forward model $e^r(\mathbf{r}_p^r, t_{pq}; \underline{h})$ is a nonlinear function of the coefficients \underline{h} . Therefore, the cost functional in (5) is generally *non-convex* with respect to \underline{h} and may have multiple local minima which correspond to *false solutions*. Standard descent-based optimization techniques (e.g., conjugate gradient [9]) can be trapped unless an accurate initial guess is available. For the narrow-band step-frequency configuration in [6], the smoothness of the cost functional was found to be essentially dependent on the frequency content of the excitation field, and a multi-resolution *frequency-hopping* strategy [10] was devised to achieve the global optimization (see [6, Sec. III-C] for details). The same guidelines can be exploited for the pulsed excitation of interest here, with the pulse length cT now playing the key role. In particular, *short* pulses are desirable to enhance resolution and accuracy in the reconstruction, but an exceedingly wide-band excitation would most likely yield a highly non-convex cost functional with many local minima, whose global minimization could become computationally unfeasible. In our numerical investigation, we found that values of $cT \lesssim 0.2d$ tend to ensure local minima in the cost functional, whereas for $cT \gtrsim 0.5d$, the achieved resolution deteriorates. Moreover, for the eventual underground imaging problem of interest (see [5]), it is also essential to achieve adequate soil penetration, and therefore operate at sufficiently low frequencies. In principle, one could gain more flexibility by using different sets of pulses for the surface estimation (e.g., implementing multi-resolution optimization strategies as in [6]) and for the underground imaging, at the expense of hardware complexity. However, in our numerical experiments, we found that a *single* pulse in the typical UWB GPR frequency range (e.g., $cT \sim 0.4d$,

i.e., $T \sim 1.3\text{ns}$ for $d = 1\text{m}$) can be used for *both* surface estimation *and* underground imaging of shallowly buried targets (see [5]), thus having the potential of yielding a reasonable trade-off between the above contrasting requirements.

V. NUMERICAL RESULTS

As mentioned earlier, the needed reflected field observation data in (5) were simulated via a reliable full-wave solution of the forward scattering problem, based on the time-harmonic multifilament current method in [11] and the fast Fourier transform (see [4, Sec. V-A] for details). Forward predictions in (5) were generated via the PO-PB model in (3) with $d/L = 40$ beams, for which the accuracy was preliminarily verified.

We begin with a simplified configuration where we use as a template for inversion *the same* spline model that was used for *generating* the actual profile. In other words, we assume *a priori* knowledge of the scale parameter Δ_x in (4) (i.e., the number of B-spline basis functions), and focus on retrieving the unknown coefficients h_n only. This somewhat unrealistic assumption will be removed subsequently via an iterative *adaptive* framework. In all simulations below, a cosine-tapered normally-incident excitation was used with $g(x) = \cos(\pi x/d)$, $\theta_A = x_A = 0$, and a single fourth-order Rayleigh pulse with $cT = 0.4d$ (Fig. 2a), which was found to provide a good compromise between resolution and smoothness in the cost functional. An observation time window $[T_p^{(on)}, T_p^{(off)}]$ with $cT_p^{(on)} = 0.3d$ and $T_p^{(off)} = 0.8d$ was used, so as to roughly gate out scattering contributions from possible targets buried deeper than $\sim 8\text{cm}$ below nominal ground ($z = 0$). The resulting cost functional in (5) was minimized via the Polak-Ribiere version of the conjugate gradient (CG) algorithm (particularly suited for non-quadratic functions [9]). The needed gradient of J was computed using a central difference formula, resulting in $2N_h + 8$ functional evaluations (i.e., $2N_h + 8$ solutions of a forward scattering problem), $N_h + 4$ being the number of unknown spline coefficients in (4). Loose *a priori* knowledge was exploited by using as an initial guess a flat interface at $z = 0$ (i.e., $\underline{h} = \underline{0}$) and restricting the surface profile search to $\pm 8\text{cm}$ around it.

A typical reconstruction example is shown in Fig. 2b. The surface profile realization was generated using the quartic spline model in (4) with random coefficients. Although no specific roughness model (e.g., Gaussian) was simulated, geometric and constitutive

parameters were selected so as to mimic natural moderate roughness with maximum-to-minimum height ~ 4 cm and maximum slope $\sim 32^\circ$ for a class of realistic soils [12]. The reconstruction is reasonably accurate throughout most of the interval, except near the edges of the illuminated region. The likely explanation for this loss of accuracy, also observed in [6], is due to the weak illumination in these regions, attributed to the aperture field (cosine) tapering which was, however, required to avoid numerical artifacts (edge effects). This kind of accuracy was observed in many numerical experiments, with numerical convergence of the minimization algorithm typically achieved within ~ 30 CG iterations (see Fig. 2c), resulting in computing times of ~ 55 secs.

In order to assess the reliability of the surface profile estimation algorithm, we performed a number of sensitivity tests with respect to possible uncertainty in the prior knowledge as well as corruption in the observed data. Figure 3 displays typical reconstructions obtained by introducing a $\pm 10\%$ error in the values of the soil parameters ϵ_{r1} and σ_1 used in the forward scattering model, and by using observation data corrupted by a $\pm 10\%$ uniform noise. As one can see, the surface estimation algorithm turns out to be remarkably robust.

Finally, to remove the unrealistic perfectly-matched-template assumption, we now invoke an adaptive iterative framework for estimating the surface profile in Fig. 2b, which was generated via the B-spline model in (4) with $N_h = 16$, by postulating a *mismatched* spline template (i.e., $N_h \neq 16$). Referring to Fig. 4, the procedure is started with a tentative initial coarse parameterization ($N_h = 6$) and the usual flat-interface ($z = 0$) initial guess for the profile, which leads to the corresponding gross-scale reconstruction in Fig. 4a. The resolution is gradually increased, utilizing at each stage the previous stage reconstruction as the initial guess. Figures 4b-d, for instance, show the iterative improvements obtained via the sequence $N_h = 12, 18, 24$ (deliberately chosen so as to avoid the perfectly matched case $N_h = 16$), with the spline parameterization progressively tuned so as to capture the various details in the surface profile. The accuracy in the last stage reconstruction (Fig. 4d) is comparable to that achieved with a perfectly matched template (Fig. 2b). In this example, a pragmatic stopping criterion was used, based on the (in)sensitivity of the cost functional with respect to further increases in N_h (see Fig. 4 caption). More systematic approaches based, e.g., on the *minimum description length*

principle, can be found in [13]. Also, more flexible *multi-scale* parameterizations can be exploited in principle to deal with more complex surface profiles, but this is outside the scope of the present paper.

VI. CONCLUSIONS

In this communication, we have presented a novel inversion algorithm for the reconstruction of moderately rough dielectric interfaces using space-time sparsely sampled reflected field data. The proposed algorithm was found to provide fast, accurate and robust estimations for moderate roughness ($\sim 4\text{cm}$ maximum-to-minimum, maximum slopes $\lesssim 30^\circ$), even for noisy data and with imperfect knowledge of soil parameters. These results lay the foundation for the adaptive techniques for subsurface GPR image reconstruction of shallowly buried plastic mine-like targets in the presence of rough air-soil interfaces addressed in [5]. Extensions presently under investigation include generalization to fully 3D geometries.

Abstract

An adaptive framework is presented for ultra-wideband ground penetrating radar imaging of shallowly-buried low-contrast dielectric objects in the presence of a moderately rough air-soil interface. The proposed approach works with sparse data and relies on recently developed Gabor-based narrow-waisted Gaussian beam algorithms as fast forward scattering predictive models. First, a nonlinear inverse scattering problem is solved to estimate the unknown coarse-scale roughness profile. This sets the stage for adaptive compensation of clutter-induced distortion in the underground imaging problem, which is linearized via Born approximation and subsequently solved via various *pixel-based* and *object-based* techniques. Numerical simulations are presented to assess accuracy, robustness and computational efficiency. The proposed approach has potential applications to antipersonnel land mine remediation.

Keywords

Ground penetrating radars, rough surfaces, Gaussian beams, short pulses, total variation, curve evolution.

I. INTRODUCTION

The problem of detecting and localizing buried objects via ground penetrating radar (GPR) has received considerable attention in recent years, with potential applications ranging from non-destructive testing to environmental remediation. In this context, one of the most important and difficult applications is related to the clearance of buried unexploded ordinance, such as plastic antipersonnel land mines [1]. Attacking such a problem requires a judicious blend of efficient physics-based modeling and advanced signal processing. The associated electromagnetic (EM) model involves wave propagation in inhomogeneous, lossy, dispersive media, and “near-field” scattering from irregularly-shaped objects and interfaces. From a signal processing perspective, the main challenges are related to the limited-viewing geometry, the low permittivity contrast of the target with respect to the background soil (i.e., low signal-to-noise ratio), the imperfect knowledge of geometric and constitutive properties of soil and targets, and the possible presence of clutter which obscures the useful signals. In particular, the effect of the rough air-ground interface, in terms of backscattered clutter and distortion introduced into the interrogating signal on its way to and from the targets of interest, is a key issue from both the EM and signal processing perspectives. In this connection, standard approaches tend to be *fully statistical*,

modeling such effects as additive colored Gaussian noise whose features are typically estimated via full-wave Monte Carlo simulations with many random soil realizations. These approaches have been explored in [2]–[5], yielding reasonably good results for the *detection* problem in the presence of small roughness. However, their accuracy and reliability turn out to be not completely satisfactory in underground imaging algorithms aimed at *localizing* and possibly *classifying* a target (see, e.g., [6]).

In an ongoing series of recent investigations, so far restricted to two-dimensional (2D) geometries and moderate roughness, we have been exploring a novel *adaptive* framework, based on prior estimation of the unknown coarse scale roughness profile and subsequent compensation for the deterministic features of the related clutter. In a stepwise approach toward constructing the necessary tools, in both the frequency (FD) and time (TD) domains, we first developed physics-based fast forward algorithms for scattering from, and transmission through, moderately rough dielectric interfaces, generalizing previously developed Gabor-based narrow-waisted Gaussian beam (GB) methods [7]–[9]. The resulting models [10], [11] have subsequently been incorporated in inverse scattering scenarios aimed at enhancing the underground imaging by compensating for the coarse scale deterministic features of the roughness profile. In particular, FD and TD surface estimation algorithms working with sparse data have been explored in [12] and [13], respectively. These techniques were found to provide reasonably accurate and robust estimations, even with noisy data and imperfect knowledge of soil parameters, requiring modest computational effort. Applications to frequency-stepped GPR subsurface imaging have been explored in [14].

The present paper is concerned with the application of the Gabor-based Physical-Optics Pulsed-Beam (PO-PB) forward scattering model in [11] and the surface estimation technique in [13] to the problem of imaging of shallowly buried plastic mine-like targets in the presence of rough air-soil interfaces, working with TD sparse data. Many GPR systems operate with short-pulse excitation. Although one could still process the data in the FD via Fourier transform, a *direct* approach in the TD offers potential advantages, including the possibility of carrying out *selective* imaging via suitable *time-windowing* of the data. Accordingly, in our problem, we shall exploit the (usually small) separation between the rough interface and the target by performing first the surface estimation via early-time

response processing (as discussed in [13]), with subsequent compensation for the roughness effect and eventual target imaging via late-time response processing. In this connection, we shall utilize the weak-scattering Born approximation to linearize the inversion problem, and explore various regularization techniques to cope with its inherent ill-posedness.

The layout of the paper is as follows. Section II introduces the rough surface underground imaging problem with TD GPR sparse data. Section III gives a short review of the surface estimation algorithm in [13]. Section IV describes the linearized forward scattering model in the presence of a *known* rough interface, and its narrow-waisted GB implementation. Section V addresses the underground imaging inversion problem and the various regularization techniques explored. Section VI details the outcomes of numerical experiments to assess the accuracy and reliability of the proposed approach, as well as its computational efficiency. Conclusions follow in Section VII. Figure 1 shows a schematic flow-chart of the proposed framework, coordinated with the paper layout, which illustrates how the various models and techniques described in the paper are combined to attack the end-to-end problem.

II. STATEMENT OF THE PROBLEM

The problem geometry is sketched in Fig. 2: in an (x, z) two-dimensional (2D) coordinate space, a target with dielectric permittivity ϵ_{r2} and negligible conductivity σ_2 is buried in a lossy homogeneous dielectric halfspace (soil) of known relative permittivity ϵ_{r1} and weak conductivity σ_1 , bounded by a moderately rough interface with profile $z = h(x)$. The target region in the halfspace $z < h(x)$ is denoted by \mathcal{D} . As stated previously, we are mainly interested in shallowly buried plastic mine-like targets, which are essentially lossless ($\sigma_2 \approx 0$) and may have dielectric properties very close to those of the background soil, i.e., $|\epsilon_{r2} - \epsilon_{r1}|/\epsilon_{r1} \ll 1$. In what follows, the wavenumbers in free space and soil will be denoted by $k_0 = \omega\sqrt{\epsilon_0\mu_0}$ and $k_1 = k_0\sqrt{\epsilon_{r1} + i\sigma_1/(\omega\epsilon_0)}$, respectively, with ω representing the angular frequency, and ϵ_0, μ_0 denoting the free-space permittivity and permeability, respectively.

The soil is illuminated by a y -directed (TM-polarized) pulsed field generated by a (projected) large truncated aperture field distribution of width d at $z = z_A$. As typical of many ultra-wideband (UWB) GPR systems, we assume that the incident field is sufficiently well-

collimated so that it can be approximated by a pulsed truncated tapered plane wave,

$$e^i(\mathbf{r}, t) \sim g(x_B)p(t - c^{-1}z_B), \quad (1)$$

with FD spectrum

$$E^i(\mathbf{r}, \omega) \sim g(x_B)P(\omega)\exp(ik_0z_B). \quad (2)$$

In (1) and (2), $\mathbf{r} \equiv (x, z)$, $p(t)$ is a short pulse of length $T \ll d/c$ with FD spectrum $P(\omega)$, $c = (\epsilon_0\mu_0)^{-1/2}$ is the free-space wavespeed, $g(x_B)$ is a spatial taper and (x_B, z_B) are beam centered coordinates,

$$\begin{bmatrix} x_B \\ z_B \end{bmatrix} = \begin{bmatrix} \cos \theta_A & \sin \theta_A \\ \sin \theta_A & -\cos \theta_A \end{bmatrix} \begin{bmatrix} x - x_A \\ z - z_A \end{bmatrix}, \quad (3)$$

with θ_A and x_A denoting the tilt angle of the radiated beam relative to the z -axis and its spatial displacement, respectively. Parameters are chosen so that the illumination tapers to zero for $|x| \leq d/2$ and vanishes for $|x| > d/2$ (Fig. 2). Here and henceforth, capital letters identify FD quantities, whereas lower case letters are used for TD quantities; FD and TD quantities are related through the following Fourier transform pair

$$f(\mathbf{r}, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} F(\mathbf{r}, \omega) \exp(-i\omega t) d\omega, \quad F(\mathbf{r}, \omega) = \int_{-\infty}^{\infty} f(\mathbf{r}, t) \exp(i\omega t) dt. \quad (4)$$

Apart from the presence of the target, the geometry and notation are the same as in [11] and [13], to which we shall refer frequently throughout the paper. Notationally, we shall use $(\alpha.\beta)$ to denote eq. (β) in ref. $[\alpha]$; for instance, (3.8) means eq. (8) in ref. [3]. As in [11] and [13], the soil is assumed to be slightly lossy, i.e., $\sigma_1 \ll \epsilon_{r1}/(\Omega_0\epsilon_0)$, with Ω_0 denoting the center angular frequency of the pulse $P(\omega)$.

The actual goal of this investigation is the *imaging* of an underground test domain (e.g., $\mathcal{D}^{(test)}$ in Fig. 2), i.e., the estimation, from sparse TD scattered field observations, of its dielectric properties in order to localize and classify possible anomalies. To this end, the y -directed scattered electric field is sampled at N_t time instants at N_r fixed receiver locations $x_1^r, \dots, x_{N_r}^r$ on the plane $z = z^r$ (Fig. 2) to obtain a set of observations. The *known term* in the problem is this set of $N_r \times N_t$ samples. In our numerical experiments

in Sec. VI, we shall use synthetic field observation data generated via a rigorous full-wave solution of the forward scattering problem (see Sec. VI-A).

III. ROUGH SURFACE PROFILE ESTIMATION

In principle, the problem of estimating the coarse-scale roughness profile of the air-ground interface can be addressed with various technologies (e.g., acoustics, laser, SAR, etc.). In [13], we proposed a simple strategy based on the processing of the *early-time* response of a UWB GPR system sampled at a limited number of receivers. Our approach is based on a compact low-dimensional spline parameterization of the roughness profile, which provides implicit regularization mitigating the inherent ill-posedness of the problem, and on the Physical-Optics Pulsed-Beam (PO-PB) forward scattering model in [11] to generate predictions of the reflected field at the receivers. The estimation problem is thus converted into a nonlinear optimization problem aimed at retrieving the unknown spline coefficients via minimization of a least-square error functional that involves the PO-PB forward scattering prediction and the available observed data. The observation time windows are chosen so as to gate out the *late-time* response (i.e., causal contributions from regions beyond a critical depth) due to the possible presence there of buried targets which may produce a bias in the surface estimation. The resulting optimization problem is generally *non-convex*, and therefore the possible presence of local minima renders its numerical implementation non-trivial. Optimization strategies and computational issues are discussed in [13]. The proposed approach was found to provide accurate and robust estimations (even with noisy data and imperfect knowledge of soil parameters) with mild computational effort (typical computing time ~ 55 secs. on a 700 MHz PC).

Having established the possibility of estimating the coarse shape of the rough air-ground interface via *early-time* response processing, we now turn to the problem of underground imaging in the presence of a *known* moderately rough interface. In our investigation, incoherent scattering contributions from finer-scale roughness are not included. These finer-scale contributions are effectively dealt with through the use of additive noise models.

IV. FORWARD SCATTERING MODEL

A. Formulation

Referring to Fig. 2, the TM-polarized *total* FD field observed in free space at $\mathbf{r} = (x, z)$ can be conveniently expressed as a sum of two components – the target scattering contribution E^s and the *background field* E^b (i.e., the field in the absence of the target),

$$E(\mathbf{r}, \omega) = E^b(\mathbf{r}, \omega) + E^s(\mathbf{r}, \omega), \quad (5)$$

with E^s given by [15]

$$E^s(\mathbf{r}, \omega) = \frac{\omega^2}{c^2} \iint_{\mathcal{D}} E(\mathbf{r}', \omega) G_b(\mathbf{r}, \mathbf{r}', \omega) O(\mathbf{r}', \omega) d\mathbf{r}'. \quad (6)$$

In (6), E is the *total* field in the target region, G_b represents the FD Green's function of the rough-interface dielectric halfspace, and

$$O(\mathbf{r}', \omega) = [\epsilon_r(\mathbf{r}') - \epsilon_{r1}] + i \frac{[\sigma(\mathbf{r}') - \sigma_1]}{\omega \epsilon_0} = \Delta\epsilon_r(\mathbf{r}') + i \frac{\Delta\sigma(\mathbf{r}')}{\omega \epsilon_0} \quad (7)$$

is usually referred to as the *object function*, with $\epsilon_r(\mathbf{r}')$ and $\sigma(\mathbf{r}')$ denoting the local relative dielectric permittivity and conductivity, respectively. Since the object function in (7) vanishes outside the target region \mathcal{D} , the integration in (6) is limited accordingly. The corresponding TD results, of interest in this paper, are obtained by Fourier inversion of (5) and (6),

$$e(\mathbf{r}, t) = e^b(\mathbf{r}, t) + e^s(\mathbf{r}, t), \quad (8)$$

where

$$e^b(\mathbf{r}, t) = \frac{1}{2\pi} \int_{-\infty}^{\infty} E^b(\mathbf{r}, \omega) \exp(-i\omega t) d\omega, \quad (9)$$

$$e^s(\mathbf{r}, t) = \iint_{\mathcal{D}} \Delta\epsilon_r(\mathbf{r}') u(\mathbf{r}, \mathbf{r}', t) d\mathbf{r}' + \frac{1}{c\epsilon_0} \iint_{\mathcal{D}} \Delta\sigma(\mathbf{r}') v(\mathbf{r}, \mathbf{r}', t) d\mathbf{r}'. \quad (10)$$

The kernels u and v in (10) are given by

$$u(\mathbf{r}, \mathbf{r}', t) = \frac{1}{2\pi c^2} \int_{-\infty}^{\infty} \omega^2 E(\mathbf{r}', \omega) G_b(\mathbf{r}, \mathbf{r}', \omega) \exp(-i\omega t) d\omega, \quad (11)$$

$$v(\mathbf{r}, \mathbf{r}', t) = \frac{1}{2\pi c} \int_{-\infty}^{\infty} i\omega E(\mathbf{r}', \omega) G_b(\mathbf{r}, \mathbf{r}', \omega) \exp(-i\omega t) d\omega. \quad (12)$$

Thus, in the total backscattered field (8) observed at the receivers, e^s is the *useful* signal carrying the information needed for imaging the target, whereas e^b is the interface-generated clutter. Further distortion introduced in the useful signal by the twice-traversed rough air-ground interface is accounted for in the fields E and G_b in (11) and (12). Assuming that an estimation of the rough interface profile is somehow available, one can use a full-wave forward solver, or the more efficient PO-PB forward scattering model in [11], to generate a prediction of the clutter e^b in (8) for a given pulsed excitation, and therefore *isolate* the target contribution e^s . Even removing the background clutter e^b , the relation in (10) between the scattered field at the receivers and the dielectric and conductivity inhomogeneities $\Delta\epsilon_r$ and $\Delta\sigma$ is not easily invertible, due to the presence in (11) and (12) of the total field E which is itself dependent on $\Delta\epsilon_r$ and $\Delta\sigma$ and consequently renders the problem *nonlinear*. However, for the plastic anti-personnel land mines of interest here, with dielectric properties close to those of the background soil, one can invoke the weak scattering limit via use of the Born approximation [15], where the total field E inside the target is replaced by the transmitted field E^t in \mathcal{D} , in the absence of the target. Moreover, we shall neglect the conductivity contrast contribution in (10), thus arriving at a *linear* model relating the scattered field at the receivers to the dielectric inhomogeneity $\Delta\epsilon_r$,

$$e^s(\mathbf{r}, t) \approx \iint_{\mathcal{D}} \Delta\epsilon_r(\mathbf{r}') \bar{u}(\mathbf{r}, \mathbf{r}', t) d\mathbf{r}', \quad (13)$$

$$\bar{u}(\mathbf{r}, \mathbf{r}', t) = \frac{1}{2\pi c^2} \int_{-\infty}^{\infty} \omega^2 E^t(\mathbf{r}', \omega) G_b(\mathbf{r}, \mathbf{r}', \omega) \exp(-i\omega t) d\omega. \quad (14)$$

The robust inversion of this model will be discussed in Sec. V. The limitations of the Born approximation, which neglects multibounce interactions inside the target, have been thoroughly investigated and are well documented in the technical literature (see, e.g., [16]). More sophisticated and accurate nonlinear [17], [18], iterative [19] and distorted

[20] variants could be exploited in principle, but this is outside the scope of the present investigation. For moderately lossy soils, once a first estimate of $\Delta\epsilon_r$ (and hence of \mathcal{D}) is obtained by inverting the linear model in (13) (see Sec. V), one can iteratively refine this estimate by re-introducing into (13) the neglected (Born-approximated) conductivity contribution in (10) as a *known term*.

B. Narrow-Waisted Gaussian Beam Implementation

In order to implement, and eventually invert, the TD linear model in (13) for the pulsed excitation in (1) and (2), one needs to compute the TD kernel \bar{u} in (14) at several observation points for a large number of source positions and time instants, with typical total number $\sim 10^6$ (see Sec. VI-D). As a consequence, the availability of a fast forward solver is a key ingredient for the overall computational feasibility of the proposed approach. In this scenario, the computational burdens of typical full-wave solvers (e.g., moment methods or finite differences) tend to be prohibitive, and it is therefore suggestive to resort to approximate approaches. We found that the Gabor-based narrow-waisted Gaussian beam algorithms in [11] are remarkably well-suited for this problem, and that they provide a reasonable trade-off between accuracy and computational burden. The PO-PB synthesis of plane-wave-excited fields transmitted into a rough-surface homogeneous halfspace detailed in [11] can readily be extended to deal with the subsequent irradiation from an induced line-source in the dielectric halfspace, thereby yielding a *closed form* TD expression for the kernel in (14) similar to those in [11]. However, for reasons that will become clear later on (Sec. IV-B.3), it is computationally cheaper to synthesize the transmitted field E^t and the rough-surface halfspace Green's function G_b in the FD, and then compute the TD kernel in (14) via fast Fourier transform (FFT) algorithms [21].

B.1 Transmitted Field

The computation of the field transmitted into the halfspace $z < h(x)$ in the absence of the target, under the quasi-plane-wave pulsed illumination in (2), is a problem already addressed in [11]. We therefore merely cite the final results, referring the reader to [11] for theoretical and computational details. The FD PO “equivalent current”, which generates the transmitted field, is parameterized in terms of x -domain discretized m_1 -indexed Gabor

basis functions with narrow width $L_1 \lesssim |\lambda_1| \ll d$, centered on the Gabor lattice points $x_{m_1} = m_1 L_1$, with $\lambda_1 = 2\pi/k_1$ denoting the wavelength in soil. These initial conditions generate narrow-waisted quasi-ray GBs propagating along the local refraction directions (Fig. 3). One obtains the following FD synthesis (cf. (11.21) and (11.22))

$$E^t(\mathbf{r}, \omega) \sim \frac{1}{2} \sum_{|m_1| \leq (d/2L_1)} C_{m_1}^t(\omega) \tilde{\mathcal{B}}_{m_1}^t(\mathbf{r}, \omega), \quad (15)$$

where the Gabor coefficients $C_{m_1}^t$ can be estimated efficiently by sampling the PO “equivalent current” at the lattice points,

$$C_{m_1}^t(\omega) \approx 2(L_1/\sqrt{2})^{1/2} g(x_{Bm_1}) [1 + \mathcal{R}_{m_1}^{(1)}] P(\omega) \exp[ik_0(z_{Bm_1} - x_{m_1} \sin \theta_{m_1}^i \cos \alpha_{m_1})]. \quad (16)$$

In (16), (x_{Bm_1}, z_{Bm_1}) denote the lattice points $(x_{m_1}, h(x_{m_1}))$ in the incident-beam coordinates (3), $\alpha_{m_1} = \tan^{-1}[dh(x_{m_1})/dx]$ is the local surface slope, $\theta_{m_1}^i = \theta_A - \alpha_{m_1}$ is the local incidence angle (see Fig. 3), and $\mathcal{R}_{m_1}^{(1)}$ is the local Fresnel TM plane-wave reflection coefficient for incidence from free space,

$$\mathcal{R}_{m_1}^{(1)} = \frac{\cos \theta_{m_1}^i - (\epsilon_{r1} - \sin^2 \theta_{m_1}^i)^{1/2}}{\cos \theta_{m_1}^i + (\epsilon_{r1} - \sin^2 \theta_{m_1}^i)^{1/2}}. \quad (17)$$

The CSP GB propagator $\tilde{\mathcal{B}}_{m_1}^t$ in (15) is computed efficiently via complex-source-point (CSP) paraxial asymptotics (cf. (11.30)-(11.34)),

$$\begin{aligned} \tilde{\mathcal{B}}_{m_1}^t(\mathbf{r}, \omega) &\sim ik_1 2^{5/4} \left(\frac{L_1}{8\pi k_1} \right)^{1/2} \frac{(\zeta_{m_1} - ib_{m_1}^t \cos \theta_{m_1}^t)}{(\tilde{R}_{m_1}^t)^{3/2}} \\ &\times \exp \left\{ i \left[k_1 \left(\tilde{R}_{m_1}^t + x_{m_1} \sin \theta_{m_1}^t \cos \alpha_{m_1} + ib_{m_1}^t \right) + \pi/4 \right] \right\}, \quad (18) \end{aligned}$$

where $\theta_{m_1}^t$ is the local refraction angle (see Fig. 3), related to $\theta_{m_1}^i$ and ϵ_{r1} via Snell’s law $\sin \theta_{m_1}^i = \sqrt{\epsilon_{r1}} \sin \theta_{m_1}^t$, $\zeta_{m_1} = -(x - x_{m_1}) \sin \alpha_{m_1} + [z - h(x_{m_1})] \cos \alpha_{m_1}$, and $\tilde{R}_{m_1}^t$ denotes the *complex distance*

$$\tilde{R}_{m_1}^t = \sqrt{(x_{bm_1}^t)^2 + (z_{bm_1}^t - ib_{m_1}^t)^2}, \quad \text{Re}(\tilde{R}_{m_1}^t) \geq 0, \quad (19)$$

with

$$\begin{bmatrix} x_{bm_1}^t \\ z_{bm_1}^t \end{bmatrix} = \begin{bmatrix} \cos \gamma_{m_1}^t & \sin \gamma_{m_1}^t \\ \sin \gamma_{m_1}^t & -\cos \gamma_{m_1}^t \end{bmatrix} \begin{bmatrix} x - x_{m_1} \\ z - h(x_{m_1}) \end{bmatrix}, \quad \gamma_{m_1}^t = \theta_{m_1}^t + \alpha_{m_1}, \quad (20)$$

$$b_{m_1}^t = \sqrt{\epsilon_{r1}} (L_1 \cos \alpha_{m_1} \cos \theta_{m_1}^t)^2 / \lambda_0. \quad (21)$$

The tilde \sim denotes quantities extended into complex coordinate space via the CSP method. In our numerical implementation, we found reasonably accurate syntheses with beam spacing $L_1 \sim 0.5|\lambda_1|$, where $\lambda_1 = 2\pi/k_1$ denotes the wavelength in soil. The resulting computational burden (see Sec. VI-E) was found to be about 2 times lower than the quasi-real ray-tracing scheme in [10], and about 4 times lower than standard Kirchhoff-PO implementations.

B.2 Rough-Surface Halfspace Green's Function

The next step is the Gabor-based narrow-waisted GB synthesis of the rough-surface halfspace Green's function G_b , which, in our TD-Born model in (13) and (14), represents the scattering contribution from a (infinitesimal) pixel in the target region of Fig. 2. Thus, instead of a quasi-plane-wave pulsed illumination from free space as in Sec. IV-B.1, we now have cylindrical waves impinging from underground induced source points \mathbf{r}' ,

$$G_1(\mathbf{r}, \mathbf{r}', \omega) = -\frac{i}{4} H_0^{(1)}(k_1 |\mathbf{r} - \mathbf{r}'|), \quad \mathbf{r}' \in \mathcal{D}, \quad (22)$$

with $H_0^{(1)}(\cdot)$ denoting the zeroth order Hankel function of the first kind. As in [11, Sec. III-A], the field radiated into the halfspace $z > h(x)$ is generated by an induced PO “surface current” (cf. (11.16))

$$J_{PO}^g(x, \mathbf{r}', \omega) = 2G_1(\mathbf{r}_h, \mathbf{r}', \omega) [1 + \mathcal{R}^{(2)}(x)], \quad \mathbf{r}_h \equiv (x, h(x)), \quad (23)$$

where $\mathcal{R}^{(2)}(x)$ denotes the local Fresnel TM plane-wave reflection coefficient for incidence from soil,

$$\mathcal{R}^{(2)}(x) = \frac{\sqrt{\epsilon_{r1}} \cos \alpha(x) - [1 - \epsilon_{r1} \sin^2 \alpha(x)]^{1/2}}{\sqrt{\epsilon_{r1}} \cos \alpha(x) + [1 - \epsilon_{r1} \sin^2 \alpha(x)]^{1/2}}, \quad (24)$$

with $\alpha(x) = \tan^{-1}[dh(x)/dx]$ being the local slope (Fig. 4). As in [11, Sec. III-B], it is expedient to rewrite the PO current by separating out the locally linear phase term that an incident plane wave propagating along the positive z -direction would induce on the locally tangent plane (cf. (11.17))

$$J_{PO}^g(x, \mathbf{r}', \omega) = \mathcal{J}_{PO}^g(x, \mathbf{r}', \omega) \exp[-ik_1 x \sin \alpha(x) \cos \alpha(x)]. \quad (25)$$

By Gabor-expanding the weakly phased *reduced* PO current (cf. (11.18)-(11.22))

$$\mathcal{J}_{PO}^g(x, \mathbf{r}', \omega) = J_{PO}^g(x, \mathbf{r}', \omega) \exp[ik_1 x \sin \alpha(x) \cos \alpha(x)], \quad (26)$$

the resulting transmitted field is parameterized in terms of narrow-waisted GBs launched from lattice points $(x_{m_2}, h(x_{m_2}))$, $x_{m_2} = m_2 L_2$, into the halfspace $z > h(x)$, analogous to what is done in (15). We obtain (see Fig. 4)

$$G_b(\mathbf{r}, \mathbf{r}', \omega) \sim \frac{1}{2} \sum_{|m_2| \leq (d/2L_2)} C_{m_2}^g(\mathbf{r}', \omega) \tilde{\mathcal{B}}_{m_2}^g(\mathbf{r}, \omega), \quad (27)$$

$$C_{m_2}^g(\mathbf{r}', \omega) \approx (L_2/\sqrt{2})^{1/2} J_{PO}^g(x_{m_2}, \mathbf{r}', \omega) \exp(ik_1 x_{m_2} \sin \alpha_{m_2} \cos \alpha_{m_2}), \quad (28)$$

$$\begin{aligned} \tilde{\mathcal{B}}_{m_2}^g(\mathbf{r}, \omega) &\sim ik_0 2^{5/4} \left(\frac{L_2}{8\pi k_0} \right)^{1/2} \frac{(\zeta_{m_2} - ib_{m_2}^g \cos \theta_{m_2}^g)}{(\tilde{R}_{m_2}^g)^{3/2}} \\ &\times \exp \left\{ i \left[k_0 \left(\tilde{R}_{m_2}^g + x_{m_2} \sin \theta_{m_2}^g \cos \alpha_{m_2} + ib_{m_2}^g \right) + \pi/4 \right] \right\}, \end{aligned} \quad (29)$$

$$\theta_{m_2}^g = \sin^{-1}(\sqrt{\epsilon_{r1}} \sin \alpha_{m_2}), \quad \alpha_{m_2} = \alpha(x_{m_2}), \quad (30)$$

$$\zeta_{m_2} = -(x - x_{m_2}) \sin \alpha_{m_2} + [z - h(x_{m_2})] \cos \alpha_{m_2}, \quad (31)$$

$$\tilde{R}_{m_2}^g = \sqrt{(x_{bm_2}^g)^2 + (z_{bm_2}^g - ib_{m_2}^g)^2}, \quad \text{Re}(\tilde{R}_{m_2}^g) \geq 0, \quad (32)$$

$$\begin{bmatrix} x_{bm_2}^g \\ z_{bm_2}^g \end{bmatrix} = \begin{bmatrix} \cos \gamma_{m_2}^g & -\sin \gamma_{m_2}^g \\ \sin \gamma_{m_2}^g & \cos \gamma_{m_2}^g \end{bmatrix} \begin{bmatrix} x - x_{m_2} \\ z - h(x_{m_2}) \end{bmatrix}, \quad \gamma_{m_2}^g = \theta_{m_2}^g - \alpha_{m_2}, \quad (33)$$

$$b_{m_2}^g = (L_2 \cos \alpha_{m_2} \cos \theta_{m_2}^g)^2 / \lambda_0. \quad (34)$$

Note that possible evanescent contributions arising from total reflection are not accounted for in this simple model; in case $\sin \theta_{m_2}^g > 1$, the corresponding GB is simply ignored. Also note that, as in (15), the discretization in (27) is limited to the region $|x| \leq d/2$, although now the line-source illumination does not necessarily vanish outside. However, in all numerical simulations presented in Sec. VI, it was verified that possible truncation-induced (late-time) effects were essentially negligible in the useful observation time-window. Concerning computational burden, the same considerations as in Sec. IV-B.1 apply.

B.3 Target-Scattered Field

Using the narrow-waisted GB syntheses in Secs. IV-B.1 and IV-B.2, the FD spectra of the transmitted field E^t and the rough-surface halfspace Green's function G_b are evaluated over the bandwidth of interest, and the TD Born kernel in (14) is computed via FFT [21] (see Sec. VI-B for details). Note that, in order to accommodate the evanescent spectra in the CSP GB propagators (18) and (29), the analytic signal formulation (one-side Fourier transform) should be used

$$\bar{u}(\mathbf{r}, \mathbf{r}', t) = \frac{1}{2\pi c^2} \text{Re} \left[\int_0^\infty \omega^2 E^t(\mathbf{r}', \omega) G_b(\mathbf{r}^r, \mathbf{r}', \omega) \exp(-i\omega t) d\omega \right], \quad \text{Im}(t) \leq 0. \quad (35)$$

Denoting by $N_{b1} = d/L_1$ and $N_{b2} = d/L_2$ the number of beams used in the GB syntheses (15) and (27), respectively, the computational complexity for evaluating the kernel waveform in (35), for fixed frequency and fixed observation and source locations, is thus $\mathcal{O}(N_{b1} + N_{b2})$. As mentioned earlier, a *direct* TD closed-form synthesis could also be obtained in terms of rapidly computable confluent hypergeometric functions, paralleling the procedure in [11, Sec. IV]. However, in order to keep track of the frequency dependence, this would require accounting for the element-by-element interaction between the beams in (15) and those in (27), resulting in a *double* beam summation for each space-time sample with a consequent computational complexity $\mathcal{O}(N_{b1} \cdot N_{b2})$, which would be considerably more expensive.

V. ROUGH SURFACE UNDERGROUND IMAGING

Based on the linear forward scattering model in (13) and on a number of observations of the scattered field waveforms at the receivers, an inversion scheme can be constructed to retrieve the unknown dielectric contrast $\Delta\epsilon_r$ in the test domain $\mathcal{D}^{(test)}$ to be imaged (Fig. 2). We recall that this problem is inherently ill-posed [22] and that only limited-viewing observations and approximate forward modelings are available, in addition to the unavoidable noise and measurement uncertainty of any practically conceivable implementation. As a consequence, classical linear approaches, such as diffraction tomography (see, e.g., [23], [24]), are difficult to apply, and regularization techniques are needed to restore well-posedness and achieve robust reconstructions. This type of problem is analogous to those typically arising in image processing applications such as object boundary detection and image segmentation [25], so that a whole arsenal of well-established tools is available. In this connection, we have been exploring two popular regularization approaches with *edge-preserving* capabilities, based on different parameterizations of the region under investigation.

A. Pixel-Based Reconstruction: L^p Norm Regularization

One of the simplest reconstruction approaches is based on the parameterization of the test domain to be imaged into a number of adequately small pixels, wherein the object function $\Delta\epsilon_r$ is assumed to be uniform. By discretizing the test domain $\mathcal{D}^{(test)}$ into N pixels centered at \mathbf{r}'_k , $k = 1, \dots, N$, with area Δs , the linear model in (13) can be discretized accordingly as

$$e^s(\mathbf{r}, t) \approx \sum_{k=1}^N \Delta\epsilon_r(\mathbf{r}'_k) \bar{u}(\mathbf{r}, \mathbf{r}'_k, t) \Delta s. \quad (36)$$

Assuming that the scattered field e^s is sampled at N_r receiver locations \mathbf{r}_i^r , $i = 1, \dots, N_r$, and N_t time instants t_{ij} , $j = 1, \dots, N_t$ (Fig. 2), the problem can be cast into matrix form as

$$\underline{y} = \underline{\underline{A}} \cdot \underline{x} + \underline{n}, \quad (37)$$

where the *known term* \underline{y} is a column vector containing the $N_r \cdot N_t$ space-time samples of e^s , $\underline{\underline{A}}$ is a $(N_r \cdot N_t) \times N$ matrix containing the space-time discretization of the TD kernel \bar{u} in (14), \underline{x} is a N -element column vector containing the *unknown* dielectric contrast $\Delta\epsilon_r$ at each pixel, and the *noise* vector \underline{n} accounts for measurement uncertainty and unmodeled effects. Specifically,

$$\underline{y} = [\underline{y}_1^T \quad \cdots \quad \underline{y}_{N_r}^T]^T, \quad \underline{y}_i^T = [e^s(\mathbf{r}_i^r, t_{i1}), \dots, e^s(\mathbf{r}_i^r, t_{iN_t})], \quad (38)$$

$$\underline{\underline{A}} = \begin{bmatrix} \underline{A}_{11} & \cdots & \underline{A}_{1N} \\ \vdots & \ddots & \vdots \\ \underline{A}_{N_r 1} & \cdots & \underline{A}_{N_r N} \end{bmatrix}, \quad \underline{A}_{ik}^T = \Delta s [\bar{u}(\mathbf{r}_i^r, \mathbf{r}_k', t_{i1}), \dots, \bar{u}(\mathbf{r}_i^r, \mathbf{r}_k', t_{iN_t})], \quad (39)$$

$$\underline{x} = [\Delta\epsilon(\mathbf{r}_1'), \dots, \Delta\epsilon(\mathbf{r}_N')]^T, \quad (40)$$

with $k = 1, \dots, N$, $i = 1, \dots, N_r$, and with T denoting the transpose. Typical regularization approaches convert this inverse scattering problem into an optimization problem where a cost functional, containing both data and model information from (37) and possible prior information about the object function, is minimized. Among them, total variation (TV) [26] is well-known for its *edge-preserving* capabilities and has found several applications in EM inverse scattering scenarios (see, e.g., [6], [27], [28]). Here, we use a more general approach, based on L^p norm regularization (LNR). The inversion of the linear model in (37) is posed as the minimization of the cost functional [29]

$$J_{LNR}(\underline{x}) = \|\underline{y} - \underline{\underline{A}} \cdot \underline{x}\|_2^2 + \beta_1 \|\underline{\underline{D}}_\nu \cdot \underline{x}\|_p^p + \beta_2 \|K(\underline{x})\|_2^2, \quad (41)$$

where $\|\cdot\|_2$ is the standard Euclidean norm and $\|\cdot\|_p$ ($0 < p \leq 2$) is an L^p norm [29]. In (41), the first term penalizes lack of data fidelity, while the other terms introduce some loose *a priori* knowledge about the object geometry, with β_1 and β_2 denoting regularization parameters. In particular, the second term highlights the expected piecewise smoothness in the reconstructed object function by penalizing the L^p norm of a spatial gradient operator $\underline{\underline{D}}_\nu$. In our implementation we chose [6], [30]

$$\|\underline{\underline{D}}_\nu \cdot \underline{x}\|_p^p \equiv \sum_{k=1}^N \left\{ \nu [\underline{\underline{D}}_x \cdot \underline{x}]_k^2 + (2 - \nu) [\underline{\underline{D}}_z \cdot \underline{x}]_k^2 \right\}^{p/2}, \quad (42)$$

where $\underline{\underline{D_x}}$ and $\underline{\underline{D_z}}$ denote standard first-order finite-difference operators in the horizontal and vertical direction, respectively, and the parameter ν controls the orientation preference of the smoothness regularization ($\nu = 1$ yields no orientation preference) [30]. As will be shown, a regularization with orientation preference may give better results, in view of the limited-viewing configuration of the problem, which gives rise to different resolutions achievable in the horizontal and vertical directions. The formulation in (42) reduces to Tikhonov-like regularization [31] for $p = 2$, and to TV-like regularization [26] for $p = 1$. As compared with the L^2 norm in the standard Tikhonov regularization [31], L^p norms with $0 < p \leq 1$ on the spatial gradient term in (42) penalize *large* jumps less, thus allowing sharper edges to form in the reconstructed object function and yielding visually better (less blurred) reconstructions.

The last term in (41) is related to possible prior information about the object function sign. Assuming, for instance, a *negative* value for $\Delta\epsilon_r$ in the target region, the L^2 norm of the operator K penalizes *positive* values (or viceversa) of the reconstructed object function

$$[K(\underline{x})]_k = \begin{cases} x_k, & x_k > 0, \\ 0, & x_k \leq 0. \end{cases} \quad (43)$$

In our implementation, the cost functional in (41) is minimized via an iterative procedure based on half-quadratic approximations (see [26] for details). The proper choice of the regularization parameters β_1 and β_2 in (41) is an important issue, and several strategies have been proposed (see, e.g., [32]), but this is not the focus here. Our choice of the regularization parameters was done by trial and error.

B. Object-Based Reconstruction: Curve Evolution

Object-based techniques have been widely investigated in image processing, with many important applications in problems like object boundary detection and image segmentation [25]. The basic idea underlying these approaches is to exploit parametric deformable shape models for the object function which incorporate possible *a priori* information about the target geometry. Prominent among them are *curve evolution* (CE) techniques (see, e.g., [33], [34]), where a *gradient flow* is designed which attracts initial closed curves to the target boundary. Applications of such approaches to EM inverse scattering problems have

been proposed in [35]–[37]. In particular, in [37], a CE approach is applied to UWB GPR underground imaging of shallowly buried low-contrast plastic targets in the presence of a *flat* air-ground interface. This approach is applied here to the more challenging problem of a *rough* air-ground interface. The algorithm in [37] is briefly reviewed. Assuming a scenario with a *single* homogeneous target occupying the region \mathcal{D} (Fig. 2) bounded by a continuous curve \vec{C} , the unknown permittivity contrast function can be expressed as

$$\Delta\epsilon_r(\mathbf{r}) = \overline{\Delta\epsilon_r}\Pi_{\mathcal{D}}(\mathbf{r}), \quad (44)$$

where $\overline{\Delta\epsilon_r} = \epsilon_{r2} - \epsilon_{r1}$, and $\Pi_{\mathcal{D}}$ is the characteristic function of the target region \mathcal{D} ,

$$\Pi_{\mathcal{D}}(\mathbf{r}) = \begin{cases} 1, & \mathbf{r} \in \mathcal{D}, \\ 0, & \mathbf{r} \notin \mathcal{D}. \end{cases} \quad (45)$$

The more general case of multiple connected or unconnected components is addressed in [37]. The parameterization in (44) contains *implicit* regularization, since the reconstructed object must be homogeneous. In this connection, the reconstruction task consists in estimating the target contour \vec{C} and the permittivity contrast $\overline{\Delta\epsilon_r}$. Using (44), the linear model in (13) can be rewritten as

$$e^s(\mathbf{r}, t) \approx \overline{\Delta\epsilon_r} \iint_{\mathcal{D}} \bar{u}(\mathbf{r}, \mathbf{r}', t) d\mathbf{r}'. \quad (46)$$

We assume, as in Sec. V-A, that a set of $N_r \cdot N_t$ samples of the scattered field is collected at N_r receiver locations \mathbf{r}_i^r , $i = 1, \dots, N_r$, at N_t time instants t_{ij} , $j = 1, \dots, N_t$ (Fig. 2). The problem of estimating target boundary and dielectric contrast is posed again as an optimization problem involving minimization of the following quadratic functional [37]

$$J_{CE}(\vec{C}, \overline{\Delta\epsilon_r}) = \frac{1}{2} \sum_{i=1}^{N_r} \sum_{j=1}^{N_t} (e_{ij}^s - \overline{\Delta\epsilon_r} U_{ij})^2 + \beta \int_{\vec{C}} dl. \quad (47)$$

As in (41), the cost functional in (47) contains a data fidelity term, where $e_{ij}^s = e^s(\mathbf{r}_i^r, t_{ij})$ and

$$U_{ij} = \iint_{\mathcal{D}} \bar{u}(\mathbf{r}_i^r, \mathbf{r}', t_{ij}) d\mathbf{r}'. \quad (48)$$

The second term serves as regularization by penalizing the arc-length of the estimated curve, with the choice of the regularization parameter β in (47) affecting its smoothness. Again, in our implementation, β is empirically selected by trial and error, taking into account prior expectations about target geometry (e.g., convexity).

To minimize the cost functional in (47), we use a CE approach to design a gradient flow that attracts an initial closed curve to the boundary of the target region \mathcal{D} . Given a family of smooth curves $\vec{C}(\tau)$ parameterized by τ , we search for the curve in this family and the contrast value $\overline{\Delta\epsilon_r}$ that minimize the cost functional in (47). For a given curve $\vec{C}(\tau)$, the contrast $\overline{\Delta\epsilon_r}$ must satisfy the following equation [37]

$$\frac{\partial J_{CE}(\tau, \overline{\Delta\epsilon_r})}{\partial \overline{\Delta\epsilon_r}} = - \sum_{i=1}^{N_r} \sum_{j=1}^{N_t} [e_{ij}^s - \overline{\Delta\epsilon_r} U_{ij}(\tau)] U_{ij}(\tau) = 0. \quad (49)$$

Moreover, it can be shown (see [37] for details) that the gradient direction of J_{CE} with respect to the curve $\vec{C}(\tau)$ is given by

$$\nabla_{\tau} J_{CE}(\tau, \overline{\Delta\epsilon_r}) = - \sum_{i=1}^{N_r} \sum_{j=1}^{N_t} [e_{ij}^s - \overline{\Delta\epsilon_r} U_{ij}(\tau)] \overline{\Delta\epsilon_r} \bar{u}_{ij}(\mathbf{r}'_c) \hat{\mathbf{n}}_c + \beta \kappa_c \hat{\mathbf{n}}_c, \quad (50)$$

where $\bar{u}_{ij}(\mathbf{r}'_c) = \bar{u}(\mathbf{r}'_i, \mathbf{r}'_c, t_{ij})$, \mathbf{r}'_c denotes points on the curve $\vec{C}(\tau)$, and $\hat{\mathbf{n}}_c$ and κ_c indicate the outward normal and the signed curvature of the curve at \mathbf{r}'_c , respectively [37]. To minimize the cost functional in (47), the curve $\vec{C}(\tau)$ is evolved along the direction of steepest descent, i.e., along the negative gradient of J_{CE} with respect to $\vec{C}(\tau)$,

$$\frac{d\vec{C}(\tau)}{d\tau} = -\nabla_{\tau} J_{CE}(\tau, \overline{\Delta\epsilon_r}) = \sum_{i=1}^{N_r} \sum_{j=1}^{N_t} [e_{ij}^s - \overline{\Delta\epsilon_r} U_{ij}(\tau)] \overline{\Delta\epsilon_r} \bar{u}_{ij}(\mathbf{r}'_c) \hat{\mathbf{n}}_c - \beta \kappa_c \hat{\mathbf{n}}_c, \quad (51)$$

where, for each τ , the optimal value of the contrast $\overline{\Delta\epsilon_r}$ is given by (49). For numerical implementation, the evolution in (51) is discretized in τ and stepped forward, alternatively updating the curve $\vec{C}(\tau)$ and the contrast $\overline{\Delta\epsilon_r}$ (via (49)). In our implementation, we use the level set method [38], [39] which yields a numerically efficient and stable evolution (see [37]).

As compared with pixel-based reconstruction techniques, object-based approaches like curve evolution (CE) offer several computational advantages. First is the natural incorporation of *a priori* information about target constitutive and geometric features, such

as homogeneity and shape smoothness. This allows use of efficient parametric models to describe target shape and permittivity contrast, with consequent *implicit* regularization which mitigates the ill-posedness of the problem and possibly reduces the data size required. Furthermore, it focuses on the key features of the target, which are estimated *directly* rather than extracted via postprocessing of a pixel-based image. Finally, the evolution in (51) depends on *local* properties, and the estimation of the contrast value in (49) is computationally inexpensive, resulting in an overall computational burden that tends to be lower than those of standard pixel-based approaches like LNR.

VI. NUMERICAL RESULTS

A. Reference Solution

The backscattered field observation data used as observations are simulated via a full-wave solution of the forward scattering problem. As in [11], this reference solution is based on the time-harmonic multifilament current method in [40], adapted to moderately rough interfaces. Specifically, the frequency domain (FD) spectrum of the field is evaluated at 100 different frequencies within the pulse bandwidth, without resorting to the plane wave approximation in (1) for the incident field, and with use of the full dispersive permittivity model for the soil. The sampled spectrum is first smoothed through local Padé-approximation [21] and then transformed via standard inverse fast Fourier transform (FFT) routines [21] to obtain the desired TD solution. In our numerical simulation we used a 1024-point FFT; the required TD samples were obtained by linear interpolation of the returned time series.

B. Gaussian Beam Algorithm Parameters

The Born TD kernel \bar{u} in (35), needed for computing the data fidelity term in both LNR and CE cost functionals, is first synthesized in the FD via narrow-waisted GB superposition (cf. (15) and (27)) and subsequently transformed to the TD via a 512-point FFT. In this case, the spectrum is sampled at 50 frequencies within the pulse bandwidth. All other needed frequency samples, as well as the output time waveform, are obtained via linear interpolation. The GB spacings L_1 and L_2 in (15) and (27), respectively, are chosen as half a (ambient) wavelength, i.e., $L_1 = |\lambda_1|/2$, $L_2 = \lambda_0/2$, with $\lambda_0 = 2\pi/k_0$ denoting

the free-space wavelength. This configuration was arrived at using a *pragmatic* stability criterion based on the (in)sensitivity of the outcome to further decreases of the GB spacing (i.e., increases in the number of GBs). To further improve computational efficiency, for a fixed observation point, one can rewrite the CSP GB propagators in (18) and (29) (see, e.g., (11.52)-(11.54)) to isolate frequency-independent parts that need to be computed only once.

C. Simulation Parameters

The numerical simulations that follow are based on the configuration and parameters described in Fig. 5. In this scenario (Fig. 5a), although no specific data model is used for soil, target and roughness, geometric and constitutive parameters were adjusted so as to be consistent with typical moderate roughness (maximum-to-minimum height $\sim 4\text{cm}$, maximum slope $\sim 32^\circ$), slightly lossy soil characteristics [41] ($\epsilon_{r1} = 4$, $\sigma_1 = 0.01\text{ S/m}$), and shallowly-buried plastic mine-like targets ($10\text{cm} \times 6\text{cm}$ ellipse with $\epsilon_{r2} = 3.5$ and $\sigma_2 = 0$, and with center at 10cm below nominal ground). The roughness profile was randomly generated via the quartic spline model in [13, Sec. IV]. The illumination field in (1) was chosen as a vertically incident fourth-order Rayleigh UWB pulse with $T = 1.3\text{ns}$ (Fig. 5c) and cosine tapering (Fig. 5b). This pulse length was found by trial and error to provide a good trade-off between the contrasting high-frequency requirements for good resolution (for both surface estimation and target localization) and low-frequency requirements for adequate soil penetration. Such UWB pulses typically work well for shallow burial depths and slightly lossy soils, as in our example, but may be not suitable for larger burial depths and/or soil losses.

The test domain to be imaged consists of a $20\text{cm} \times 20\text{cm}$ domain surrounding the target, with top side at 5cm below nominal ground. The backscattered field observation data needed for inversion are collected at $N_r = 11$ receivers at $z^r = 0.3\text{m}$ and $x_i^r = -0.5\text{m}, -0.4\text{m}, \dots, 0.5\text{m}$. Note that the relatively low permittivity contrast in this example ($|\Delta\epsilon_r|/\epsilon_{r1} = 0.125$), which justifies the Born approximation in (13), renders the test particularly challenging in view of the weak target scattering as compared with the interface-generated clutter. The burial depth was chosen so as to avoid the relatively clean case where ground-scattered and target-scattered signals are well time-resolved (see Sec.

VI-D).

D. Reconstruction Examples

Before testing the various underground imaging strategies, it is useful to look at the scattered waveforms at the receivers, in order to identify the various contributions and to check the accuracy of the Born-GB forward scattering model. Figure 6a shows the comparison between the total field e (soil+target) and the background field e^b (soil only) waveforms at a fixed receiver location, computed via the full-wave technique described in Sec. VI-A. The two waveforms are practically indistinguishable in the plot scale. Their difference (the target contribution e^s) is displayed in Fig. 6b and is compared with the Born-GB synthesis described in Sec. VI-B. Reasonably good agreement is observed. Looking at the different scales in the two plots, it is noted that background field removal is crucial for achieving reasonable signal-to-noise ratio in the inverse scattering procedure. For rough interfaces and shallowly-buried targets, as in this example, this cannot usually be accomplished by mere time-windowing of the data since ground-scattered and target-scattered signals are *not* well time-resolved. In this connection, the availability of rough interface profile estimations (and hence background field predictions) is of great importance.

Another important issue is the choice of the actual number of unknowns in the object parameterization. This requires trade-off between resolution, robustness and computational burden. Aside from computational considerations, it is understood that beyond a critical level, related to the *essential* dimension of the available information, any attempt at further refinement in the object discretization will increase the sensitivity to noise, *without* actually improving the resolution. The essential information entailed in the forward scattering model can be estimated roughly, for instance, via singular value decomposition (SVD) [21] of the (discretized) scattering kernel in (14), whereas the prior information introduced with the various regularization techniques cannot be easily quantified. We did not attempt to address *optimal* strategies for object discretization and data acquisition. The data and unknown configurations used in the examples, though not necessarily optimal, were found to provide a reasonable trade-off between the above contrasting requirements. In particular, to account for possible redundancy in the observed data, in all examples below we retain a data-to-unknown ratio ~ 3 .

For pixel-based reconstruction with L^p norm regularization (LNR), the test domain to be imaged was discretized into 30×30 square pixels (900 unknowns), and we used $N_t = 300$ time samples of the *late-time* response (causally related to the test domain) at each of the $N_r = 11$ receivers in Fig. 5. The observation vector \underline{y} in (38) was obtained by subtracting the PO-PB-computed background field e^b (see [11]) from the full-wave-computed total field e at each receiver; the (3300×900) data matrix \underline{A} in (39) was computed via the Born-GB algorithm (see Sec. VI-B). In all examples below, the various regularization parameters were selected pragmatically via trial and error, and the results reported correspond to the *best* reconstruction obtained. Reconstruction results, however, were found to be relatively insensitive to variation of these parameters within a calibrated range.

We now move on to presenting various examples of underground imaging results.

D.1 Perfectly Known Roughness Profile and Soil Parameters, and Noiseless Data

We start with the simplest, though somewhat unrealistic, case of perfectly known roughness profile and soil parameters, and noiseless observation data, on which we test the various reconstruction techniques presented so far. A number of representative pixel-based reconstruction examples are shown in Fig. 7. Specifically, the true object function (ground truth) is shown in Fig. 7a, while Figs. 7b-d display a number of LNR reconstructions with $p = 1$, i.e., total-variation-like (TVL), with various combinations of the regularization parameters, namely, *i*) gradient penalty without directional preference, i.e., $\beta_2 = 0$ in (41) and $\nu = 1$ in (42) (Fig. 7b); *ii*) gradient penalty with directional preference, i.e., $\beta_2 = 0$ and $\nu = 0.1$ (Fig. 7c); and *iii*) gradient penalty with directional preference and “positivity penalty”, i.e., $\beta_2 > 0$ and $\nu = 0.1$ (Fig. 7d). It is observed that all TVL images, though not yielding highly accurate point-wise reconstructions, provide reasonably accurate target localization. Note that the limited-viewing geometry (vertical illumination) renders the problem *more ill-posed* in the horizontal direction, resulting in higher vertical than horizontal resolution in all cases. In this connection, gradient penalty with *directional* preference turns out to be more effective, since the data fidelity term is less sensitive to horizontal than vertical blurring. If the gradient penalty is equally imposed on both directions (as in Fig. 7b), it is possible that the vertical direction is under-regularized while the horizontal direction is over-regularized. Therefore, a gradient penalty with $\nu < 1$ (smaller

in the horizontal direction, as in Fig. 7c) may help in compensating for this imbalance, and yield visually better reconstructions. Looking at Fig. 7d, it is realized that prior knowledge of the object function sign, and consequent positivity (or negativity) penalty in the cost functional, may further improve the reconstruction.

For more *quantitative* accuracy assessments, we introduced two simple r.m.s. error metrics in both target and background regions,

$$\Delta e_t \equiv \frac{\sum_{\mathbf{r}'_k \in \mathcal{D}} [\epsilon_{r2} - \epsilon_{r2}^{(est)}(\mathbf{r}'_k)]^2}{N_2 \epsilon_{r2}^2}, \quad \Delta e_b \equiv \frac{\sum_{\mathbf{r}'_k \notin \mathcal{D}} [\epsilon_{r1} - \epsilon_{r1}^{(est)}(\mathbf{r}'_k)]^2}{N_1 \epsilon_{r1}^2}, \quad (52)$$

where $\epsilon_{r1}^{(est)}$ and $\epsilon_{r2}^{(est)}$ denote the estimated relative permittivity in the background and target regions, respectively, while N_1 and N_2 indicate the corresponding number of pixels. These errors are specified (in dB) in the figure captions. It is observed from Fig. 7 that gradient penalty with directional preference coupled with positivity penalty (Fig. 7d) yields the smallest errors ($\Delta e_t = -22\text{dB}$, $\Delta e_b = -37\text{dB}$).

Reconstruction examples for $p = 0.5, 1.5$ and 2 (with directional preference and positivity penalty) are shown in Fig. 8. By comparing these reconstructions, together with that for the corresponding TVL (i.e., $p = 1$) in Fig. 7d, one notes progressive blurring toward the Tikhonov-like ($p = 2$, Fig. 8c) reconstruction. However, LNR with $p < 1$ (e.g., $p = 0.5$ in Fig. 8a) was found not to yield significant improvement as compared with TVL, and the corresponding results are omitted henceforth.

Figure 9 shows a reconstruction obtained via CE, which provides good estimation of both target boundary and permittivity (only 0.6% error in ϵ_{r2}). The reconstruction looks visually better than the corresponding TVL one in Fig. 7d, as also witnessed by the smaller r.m.s. errors, $\Delta e_t = -25\text{dB}$, $\Delta e_b = -39\text{dB}$, computed from (52) with the same pixelization used for LNR. Again, due to the limited-viewing configuration, localization is more accurate vertically than horizontally. For this reconstruction, a reduced data set was used, with only 6 receivers (#1, 3, 5, 7, 9, and 11, in Fig. 5) and 100 time samples each, taking advantage of the more compact object parameterization entailed in CE as compared with pixel-based reconstruction techniques.

D.2 Imperfectly Known Roughness Profile and Soil Parameters, and Noisy Data

We now explore more realistic configurations by removing the assumption of perfect knowledge of the air-soil rough interface as well as soil parameters and observation data. First, to highlight the effect of the air-ground interface roughness, so far assumed to be perfectly known, we show in Fig. 10 a TVL reconstruction obtained by *erroneously* assuming a flat air-ground interface at $z = 0$ in the forward scattering model. Image deterioration, mainly due to poor background field removal, is dramatic and renders the reconstruction practically meaningless. For this configuration, CE likewise gave meaningless results, exhibiting strong sensitivity to initial conditions and regularization parameters. Results can be improved via statistical processing, as shown in [6], but will not become comparable to those in Figs. 7–9.

Now, we use the algorithm in [13] (see also Sec. III) to generate estimations of the rough interface to be used in the subsequent underground imaging problem. We also investigate the effect of measurement uncertainty in the observation data as well as soil parameters. Figure 11 shows the rough interface reconstructions obtained with two different data configurations: *i*) corruption of the observation data with an additive uniform noise ($\pm 10\%$ in amplitude) that accounts for measurement uncertainty and unmodeled effects (e.g., finer-scale roughness scattering), and *ii*) assumption of a -5% error in ϵ_{r1} and σ_1 in the forward scattering model. For these reconstructions, as discussed in [13], we used $N_t = 50$ time samples of the *early-time* response at each of the 11 receivers in Fig. 5; the observation time-windows were chosen so as to roughly gate out scattering contributions from possible regions deeper than $\sim 8\text{cm}$ below nominal ground ($z = 0$), thus avoiding any possible bias due to target scattering. Interface estimates are reasonably accurate, apart from the weakly-illuminated edge regions, as also observed in [13]. We repeat that, for the underground imaging problem, these configurations are particularly challenging. The -5% relative permittivity mismatch in the second example is on the same order as the actual dielectric contrast $\Delta\epsilon_r = -0.5$ to be estimated. The corresponding TVL and CE target reconstructions are shown in Fig. 12, where a slightly narrower illumination ($d = 0.8\text{m}$) is used in order to de-emphasize the effect of the poorly estimated side regions in Fig. 11. Specifically, Figs. 12a and 12b show TLV and CE reconstructions, respec-

tively, for the case of noisy data (with perfectly known soil parameters), whereas Figs. 12c and 12d show the corresponding results for the case of imperfectly known soil parameters (with noiseless data). In these examples, the corresponding estimated air-soil interface profiles in Fig. 11 are used in the forward scattering model. As seen from Figs. 12a and 12b, reconstructions turn out to be robust with respect to noise in the observation data. In particular, CE still yields good target localization and permittivity estimation (1.7% error in ϵ_{r2} ; $\Delta e_t = -23\text{dB}$, $\Delta e_b = -39\text{dB}$). For the TVL reconstruction, r.m.s. errors ($\Delta e_t = -21\text{dB}$, $\Delta e_b = -31\text{dB}$) are still comparable to those obtained in the *ideal* case (Fig. 7d). For the more challenging soil-parameter-mismatch test in Figs. 12c and 12d, although the target shape is not as accurately captured as before, localization and permittivity estimation (1.7% error in ϵ_{r2} , and $\Delta e_t = -26\text{dB}$, $\Delta e_b = -25\text{dB}$ with CE; $\Delta e_t = -15\text{dB}$, $\Delta e_b = -22\text{dB}$ with TVL) are still acceptable for classification purposes. We stress that this latter test is particularly meaningful since the assumed mismatch in the soil parameters reduces the *effective* visibility of the (already low-contrast) target, thus also emphasizing the effect of imperfect background field removal. However, it is understood that for such low-contrast target scattering scenarios, *stronger* uncertainty in the soil parameters may render the target practically invisible.

E. Computational Aspects

The overall computational features of the proposed approach are detailed in Table I for each of the separate tasks required, with specific reference to a 700 MHz PC benchmark implementation. The computational burdens of the first four tasks are strongly tied to those of the narrow-waisted GB forward solvers in [11] and Secs. IV-B and VI-B. In this connection, the reported (average) computing times were found to be about four times and two times smaller than those achievable with standard PO implementations the quasi-real ray tracing in [10], respectively. Meaningful comparisons with full-wave forward solvers are not easy since computational features may be strongly implementation-dependent. To give a rough idea, the (estimated) computing times for estimating the air-soil interface and for building up the forward model (data matrix filling up) when using our full-wave reference solution in the forward scattering models would have been on the order of eight and four hours, respectively. These rough estimates are based on forward scattering benchmark

simulations.

As seen from Table I, the only memory-demanding tasks are those involving the manipulation of the LNR data matrix $\underline{\underline{A}}$ in (41) and a similar (but smaller) data matrix used in the CE (51) via the level set method.

Overall, CE tends to be computationally cheaper than LNR. Although the numerical codes are not fully optimized, overall computing times are on the order of a few minutes, thus leaving room for optimism that extensions of the algorithmic approach to more realistic three-dimensional (3D) scenarios will remain computationally affordable for real-world applications.

VII. CONCLUSIONS

An adaptive approach for underground imaging via ultrawide-band ground penetrating radar in the presence of a moderately rough air-soil interface has been presented. The proposed approach is based on short-pulse Gabor-based narrow-waisted Gaussian beam algorithms as fast forward scattering models, through which the coarse-scale deterministic features of the air-ground interface are first estimated and subsequently exploited to compensate for background clutter and distortion in the interrogating signal. Preliminary 2D results, restricted to slightly lossy soils and shallowly-buried low-contrast dielectric targets, indicate that quite accurate and robust target reconstructions can be obtained with reasonable computing times and resources, even with sparse and corrupted data and imperfect knowledge of soil parameters. The proposed approach looks promising from both the computational and accuracy viewpoints, with potential application to antipersonnel land mine clearance. In this connection, the necessary extension to more realistic 3D configurations, currently under investigation, is fairly straightforward theoretically, but its computational features remain to be explored. Also under investigation are more robust strategies for background field removal.

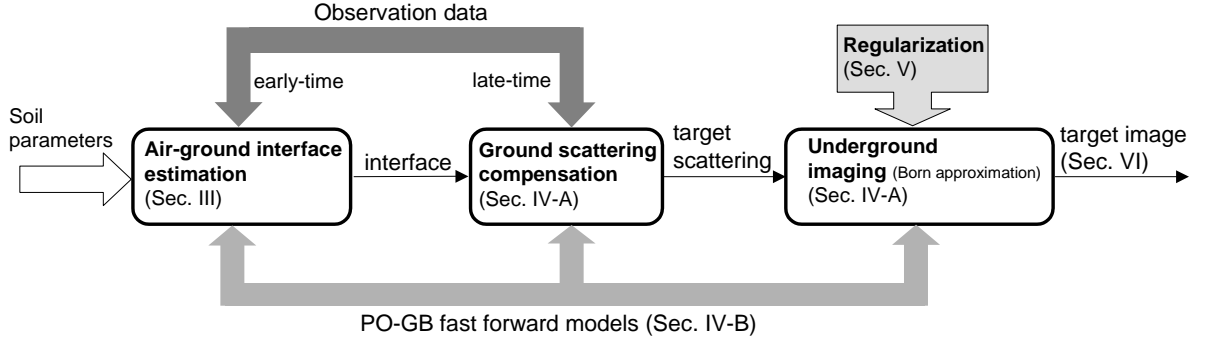

Fig. 1. Schematic flow-chart of the proposed adaptive approach, coordinated with the paper layout.

Fig. 2. Problem geometry. An aperture-generated, quasi-plane-wave, TM-polarized pulsed field impinges from free space onto a dielectric halfspace with known relative permittivity ϵ_{r1} and conductivity σ_1 , bounded by a moderately rough interface profile $z = h(x)$, wherein a target with dielectric permittivity ϵ_{r2} and conductivity $\sigma_2 \approx 0$ occupies the region \mathcal{D} . In order to image the test domain $\mathcal{D}^{(test)}$, the reflected field is sampled at N_t time instants at N_r fixed receiver locations $x_1^r, \dots, x_{N_r}^r$ on the observation plane $z = z^r$.

Fig. 3. Global and local coordinates for beams transmitted from free space into the soil. $(x_{bm_1}^t, z_{bm_1}^t)$ is the m_1 -th transmitted-beam-centered local coordinate system; (ξ_{m_1}, ζ_{m_1}) is the local tangent-normal coordinate system, centered at lattice points $(x_{m_1}, h(x_{m_1}))$; $\alpha_{m_1} = \tan^{-1}[dh(x_{m_1})/dx]$ is the local slope; $\theta_{m_1}^t$ is the local refraction angle measured from the surface normal; $\gamma_{m_1}^t = \theta_{m_1}^t + \alpha_{m_1}$ is the local refraction angle measured from the z -axis.

Fig. 4. As in Fig. 3, but for beams transmitted from soil into free space, with planar approximation of the incident cylindrical wavefront in (22). $(x_{bm_2}^g, z_{bm_2}^g)$ is the m_2 -th transmitted-beam-centered local coordinate system; $\theta_{m_2}^g$ is the local refraction angle measured from the surface normal; $\gamma_{m_2}^g = \theta_{m_2}^g - \alpha_{m_2}$ is the local refraction angle measured from the z -axis.

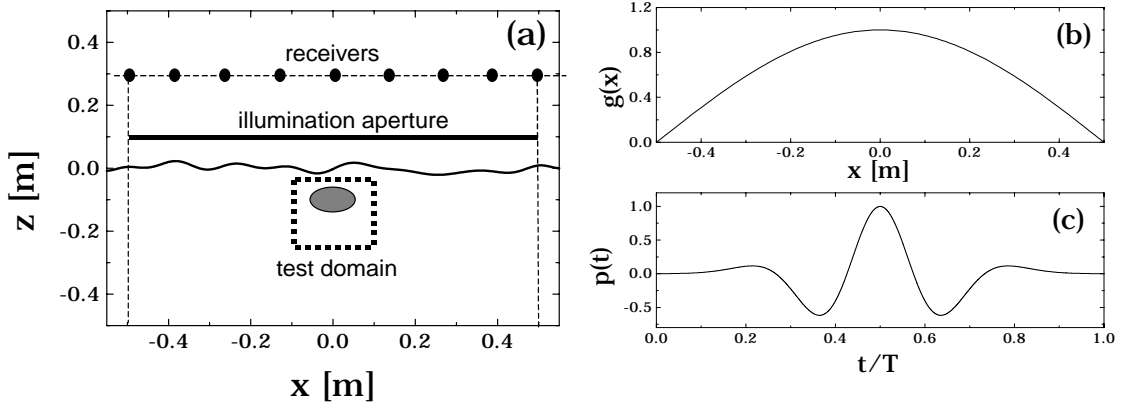

Fig. 5. Simulation geometry and parameters (cf. Fig. 2). (a): An elliptic ($10\text{cm} \times 6\text{cm}$) dielectric mine-like target with $\epsilon_{r2} = 3.5$ and $\sigma_2 = 0$ is buried with center at 10cm below the nominal ground ($z = 0$). The rough surface profile realization was randomly generated so as to simulate typical moderate roughness (maximum-to-minimum height $\sim 4\text{cm}$, maximum slope $\sim 32^\circ$) for a class of realistic soils ($\epsilon_{r1} = 4$, $\sigma_1 = 0.01\text{ S/m}$). A $20\text{cm} \times 20\text{cm}$ test domain surrounding the target (with top side at 5cm below nominal ground) is to be imaged. The reflected field is sampled at $N_r = 11$ receivers located at $z^r = 0.3\text{m}$ and $x_i^r = -0.5\text{m}, -0.4\text{m}, \dots, 0.5\text{m}$. (b): Incident field tapering $g(x) = \cos(\pi x/d)$. Parameters: $d = 1\text{m}$, $\theta_A = 0$, $x_A = 0$, $z_A = 0.1\text{m}$. (c): Fourth-order Rayleigh pulsed excitation $p(t)$ ($cT = 0.4d$, i.e., $T \sim 1.3\text{ns}$).

Fig. 6. Parameters as in Fig. 5. Field observed at receiver #8 ($x_8^r = 0.3\text{m}$, $z^r = 0.3\text{m}$) (a): — Total field e (reference solution); - - - Background field e^b (reference solution). Both are coincident on this drawing. (b): Target-scattered field $e^s = e - e_b$. — Reference solution; - - - Beam-Born approximation in (13) (parameters as in Sec. VI-B).

Fig. 7. Parameters as in Fig. 5. (a): Ground truth ($\Delta\epsilon_r$ reference configuration). (b): TVL ($p = 1$) reconstruction ($\beta_1 = 1.6 \cdot 10^{-6}$, $\nu = 1$, $\beta_2 = 0$; $\Delta e_t = -19\text{dB}$, $\Delta e_b = -35\text{dB}$). (c): TVL reconstruction with directional preference ($\beta_1 = 4.6 \cdot 10^{-6}$, $\nu = 0.1$, $\beta_2 = 0$; $\Delta e_t = -19\text{dB}$, $\Delta e_b = -35\text{dB}$). (d): TVL reconstruction with directional preference and positivity penalty ($\beta_1 = 3.4 \cdot 10^{-6}$, $\nu = 0.1$, $\beta_2 = 2 \cdot 10^{-3}$; $\Delta e_t = -22\text{dB}$, $\Delta e_b = -37\text{dB}$). The exact air-soil interface profile is used in the forward scattering model.

Fig. 8. As in Fig. 7, but using LNR with $p \neq 1$, directional preference and positivity penalty ($\beta_1 = 3.4 \cdot 10^{-6}$, $\nu = 0.1$, $\beta_2 = 2 \cdot 10^{-3}$). (a): $p = 0.5$ ($\Delta e_t = -22\text{dB}$, $\Delta e_b = -40\text{dB}$). (b): $p = 1.5$ ($\Delta e_t = -23\text{dB}$, $\Delta e_b = -33\text{dB}$). (c): $p = 2$ (Tikhonov, $\Delta e_t = -24\text{dB}$, $\Delta e_b = -27\text{dB}$). The case $p = 1$ (TVL) is displayed in Fig. 7d.

Fig. 9. Parameters as in Fig. 5. Curve evolution reconstruction (white curve) is superposed on ground truth. Curve initial conditions are displayed by dashed lines. Evolution parameters: 150 steps with $\beta = 3.5 \cdot 10^{-5}$ plus 620 steps with $\beta = 0.3 \cdot 10^{-5}$. The estimated target relative permittivity is $\epsilon_{r2} = 3.52$ (0.6% error). The r.m.s. errors in target and background regions are $\Delta e_t = -25\text{dB}$ and $\Delta e_b = -37\text{dB}$, respectively. The exact air-soil interface profile is used in the forward scattering model.

Fig. 10. As in Fig. 6d ($\beta_1 = 3.4 \cdot 10^{-6}$, $\nu = 0.1$, $\beta_2 = 2 \cdot 10^{-3}$), but assuming a flat interface at $z = 0$ in the forward scattering model ($\Delta e_t = 27\text{dB}$, $\Delta e_b = 28\text{dB}$).

Fig. 11. Parameters as in Fig. 5. Rough surface profile reconstruction via early-time response processing (cf. Sec. III and [13]). The early-time field at the receivers is sampled at $N_t = 50$ time instants with the observation windows chosen so as to roughly gate out causal scattering contributions from regions deeper than $\sim 8\text{cm}$ below nominal ground. — Actual profile; - - - Reconstruction with observation data corrupted by a $\pm 10\%$ additive uniform noise; ····· Reconstruction with -5% error in ϵ_{r1} and σ_1 .

Fig. 12. Parameters as in Fig. 5, but with $d = 0.8$. Reconstruction examples with corrupted data via TVL regularization and CE. (a): TVL reconstruction with field data observations corrupted by $\pm 10\%$ additive uniform noise ($\beta_1 = 3.4 \cdot 10^{-6}$, $\nu = 0.1$, $\beta_2 = 2 \cdot 10^{-3}$, $\Delta e_t = -21\text{dB}$, $\Delta e_b = -31\text{dB}$). (b): As in Fig. 12a, but CE reconstruction (white curve) superposed on ground truth (150 steps with $\beta = 3.5 \cdot 10^{-5}$ plus 627 steps with $\beta = 0.3 \cdot 10^{-5}$; estimated target permittivity: $\epsilon_{r2} = 3.56$, i.e., 1.7% error; $\Delta e_t = -23\text{dB}$, $\Delta e_b = -39\text{dB}$). (c): TVL reconstruction with -5% error in ϵ_{r1} and σ_1 ($\beta_1 = 3.4 \cdot 10^{-6}$, $\nu = 0.1$, $\beta_2 = 2 \cdot 10^{-3}$, $\Delta e_t = -15\text{dB}$, $\Delta e_b = -22\text{dB}$). (d): As in Fig. 12c, but CE reconstruction (white curve) superposed on ground truth (150 steps with $\beta = 3.5 \cdot 10^{-5}$ plus 640 steps with $\beta = 0.21 \cdot 10^{-5}$; estimated target permittivity: $\epsilon_{r2} = 3.56$, i.e., 1.7% error; $\Delta e_t = -26\text{dB}$, $\Delta e_b = -25\text{dB}$). The *estimated* air-soil interface profiles in Fig. 11 are used in the forward scattering model.

ABSTRACT

In this paper, we work towards a robust approach for imaging weak-contrast objects buried under a rough soil/air interface using data from an electromagnetic GPR (ground penetrating radar) array. A major source of variability in observed GPR signals is due to reflection from a rough and random ground. Our approach to imaging is based on use of physical and statistical modeling techniques to estimate and compensate for this rough soil/air interface. An approximate physical model based on Gaussian beams is used to model the interaction of the illumination with the ground and estimate the surface profile. This estimated surface profile is then used to correct the raw data for the effects of the rough surface. The corrected data may subsequently be used to reconstruct the subsurface region and localize anomalies. In this stage, statistical models can be used to account for both noise and residual unmodeled effects.

Keywords: Ground penetrating radars, rough surfaces, Gaussian beams

1. INTRODUCTION

In applications such as humanitarian demining, one is interested in detecting shallowly buried small objects with conductivity properties which differ slightly from the surrounding medium. When using ground penetrating radar (GPR) signals, a major source of variability in the received signals is due to reflections from the variable, unknown surface profile. Since the objects of interest are shallowly buried, the backscattered signals from the subsurface objects are difficult to separate from the stronger surface reflections.

In this paper, we work towards a robust approach for imaging weak-contrast objects buried under a rough soil/air interface using data from an electromagnetic GPR array. In particular, we are interested in the use of physical and statistical modeling techniques to estimate and compensate for the effects of unknown air/soil interfaces. We propose to estimate the nature of this interface, and use the estimated characteristics to isolate the return obtained by subsurface scattering. We use an approximate physical model based on Gaussian beams to model the reflected and transmitted fields at the air/soil interface parametrically, in terms of an unknown ground shape. The Gaussian beam model is fast, which allows for real-time generation of parameter estimates. Based on the received signals at the GPR array and the field models, we obtain an estimated surface profile, which is then used to correct the received data to compensate for the effects of the rough surface.

The corrected data may subsequently be used to reconstruct the subsurface region and localize anomalies. In this stage, statistical models can be used to account for noise, estimation error and residual unmodeled effects. In the present paper we present the Gaussian beam air/soil interaction model, and the resulting estimation algorithm for surface profile. We outline the subsequent steps on how the subsurface imaging process would proceed. We plan to evaluate this algorithm on experimental data collected at Northeastern University's subsurface test facility using both a forward-looking and a downward-looking GPR array.

The rest of this paper is organized as follows: In the next section, we overview the formulation and solution of the rough surface reconstruction problem using our proposed Gaussian beam models. To simplify the notation and exposition, we restrict our discussions to a 2-D geometry. Extensions of the results to 3-D geometries are included in our references. In Section 3, we present the approach for constructing subsurface images using diffraction tomography ideas integrated with the Gaussian Beam models. Section 4 presents a summary and future directions for investigation.

2. ROUGH SURFACE RECONSTRUCTION

2.1. Statement of the Problem

Most available algorithms for rough surface estimation have concentrated on conducting surfaces and time-harmonic excitation, and usually require densely sampled measurements. For instance, Wombell and DeSanto¹ used Kirchhoff approximations and Fourier transforms to estimate surface profiles based on measurements of the scattered field in all spectral directions. Ying and Noguchi² used nonlinear optimization techniques for direct estimation of surfaces illuminated by monochromatic Gaussian beams, based on the far-field scattering amplitude for all spectral directions. In a different approach, Schatzberg and Devaney³ used the Rytov approximation and backpropagation to estimate surface profiles based on full measurements (amplitude and phase) of the scattered wave. In contrast with the above contributions, our investigation here is concerned with moderately rough interfaces between air and a homogeneous dielectric half space (soil), and with the estimation of the interface profile from a limited number of spatially/temporally sampled reflected field measurements, using limited aperture illumination, as is typical for realistic ground penetrating radar (GPR) configurations. In a recent investigation⁴ we addressed this problem for narrow-band stepped-frequency GPR configurations by exploiting the time-harmonic Gabor-based Gaussian beam forward scattering model in Ref. 5. Here, we extend the approach to wide-band pulsed illumination, typical of many realistic GPR systems.

The proposed extension is based on a recently developed Gabor-based narrow-waisted pulsed-beam (PB) representation of short-pulse scattering by moderately rough dielectric interfaces.⁶ The problem geometry is sketched in Fig. 1: in an (x, z) two-dimensional (2D) coordinate space, a pulsed field with transverse magnetic (TM) polarization is assumed to impinge vertically from free-space onto a lossy, homogeneous dielectric half-space (soil) of known relative permittivity ϵ_r and conductivity σ , bounded by a moderately rough interface described by the continuous function $h(x)$. We assume that the transmitting array generates a y -directed tapered well-collimated pulsed field with transverse aperture width d , which can be approximated by a pulsed truncated tapered plane wave propagating in the negative z -direction (see Fig. 1),

$$e^i(x, z, t) \sim g(x)p(t - c^{-1}z), \quad (1)$$

where $p(t)$ is a pulse of length $T \ll d/c$, with c representing the speed of light, and $g(x)$ is the taper profile.

The 2D y -directed reflected field e^r is sampled at N_t time instants at N_r receiver locations (at $z = z^r$). To begin with, we ignore the presence of buried objects and the *noisy* (incoherent) contribution of finer-scale roughness, and we seek to estimate the coarse shape of the surface, acknowledging the implicit limits of retrievable information through inverse scattering. As in Ref. 4, due to the inherent *ill-posedness* of this inverse scattering problem, we exploit a *robust* inversion strategy based on an appropriate compact low-dimensional representation of the surface, which provides an “implicit” regularization. The surface estimation problem is thus posed as a nonlinear optimization problem, whose solution requires repeated evaluations of the reflected field at the receiver locations. The efficiency of such an approach strongly relies on the availability of a fast forward scattering model. An efficient forward solver is necessary also for computing the field transmitted into the soil, as required in Born-approximation-based techniques for underground imaging later on (see Sec. 3.1).

2.2. Forward Scattering Model

The forward scattering model is detailed in Ref. 6. It is based on the Kirchhoff Physical Optics (PO) approximation in conjunction with the Gabor-based narrow-waisted PB discretization of 1D aperture field distributions in Ref. 7. In this section, we briefly review the basic theory underlying the algorithm.

In the asymptotic high-frequency range, and for smooth roughness over all wavelength scales in the pulse spectrum, the reflected field spectrum is approximated by the PO integral

$$E^r(x, z, \omega) \sim - \int_{C_{PO}} J_{PO}(x', \omega) \frac{\partial}{\partial \zeta} G(x, z; x', h(x'); k_0) d\ell', \quad (2)$$

where C_{PO} extends over the illuminated portion of the 1D interface $z = h(x)$, $d\ell'$ is the incremental arc-length measured along the surface tangent, and $\partial/\partial\zeta$ denotes the normal derivative. The incident field tapering is chosen so that the illuminated portion of the interface, C_{PO} , is essentially confined to the interval $|x| \leq d/2$. Furthermore, G is the frequency-domain (FD) line-source free-space Green’s function,

Figure 1. Setup geometry for the inverse scattering problem. A TM polarized pulsed EM field illuminates a homogeneous dielectric half-space with known relative permittivity ϵ_r and conductivity σ and with a moderately rough interface whose coarse scale profile is described by the continuous function $h(x)$. The reflected field is sampled at N_r receiver locations and N_t time instants, at $z = z^r$.

$$G(x, z; x', z'; k) = \frac{i}{4} H_0^{(1)}(kR), \quad R = [(x - x')^2 + (z - z')^2]^{1/2}, \quad (3)$$

with $H_0^{(1)}(\cdot)$ denoting the zeroth order Hankel function of the first kind. The induced PO “surface current” density J_{PO}^r is given by twice the tangential reflected field at the interface, obtained from the canonical solution of infinite plane-wave scattering by a plane dielectric boundary locally tangent to the rough surface profile

$$J_{PO}^r(x, \omega) = 2\mathcal{R}(x, \omega) E^i(x, h(x), \omega). \quad (4)$$

In (4), E^i is the frequency spectrum of (1), and \mathcal{R} denotes the local TM plane-wave Fresnel reflection coefficient,

$$\mathcal{R}(x, \omega) = \frac{\cos \theta^i - (\epsilon_r^e - \sin^2 \theta^i)^{1/2}}{\cos \theta^i + (\epsilon_r^e - \sin^2 \theta^i)^{1/2}}, \quad (5)$$

where $\theta^i(x) = -\tan^{-1}[h'(x)]$, $' \equiv d/dx$, is the local incident angle relative to the normal, and $\epsilon_r^e(\omega) = \epsilon_r + i\sigma/(\omega\epsilon_0)$ is the complex, frequency dependent, *effective* permittivity of the soil. In the following, we restrict consideration to slightly lossy soils, i.e.,

$$\frac{\sigma}{\omega\epsilon_0\epsilon_r} \ll 1, \quad \omega < \Omega, \quad (6)$$

with Ω denoting the effective bandwidth of the pulse $p(t)$. This condition is typically fulfilled in many GPR applications^{8,9} and significantly simplifies the time domain (TD) inversion.⁶

The PO radiation integral in (2) is not very different from the Kirchhoff aperture integrals analyzed in Ref. 7, except that the line integration in (2) is performed along a rough surface profile instead of on a projected equivalent planar aperture. In Ref. 7, the 1D space-time aperture field distribution is first parameterized in the FD in terms of x -domain discretized m -indexed Gabor basis functions with narrow width L , centered on the Gabor lattice points $x_m = mL$; these initial conditions generate *narrow-waisted*, quasi-ray, complex-source-point Gaussian beams. For Rayleigh pulses,

$$p(t) = \Xi \frac{d^j}{dt^j} \exp \left[- \left(\frac{t - T/2}{\zeta T} \right)^2 \right], \quad (7)$$

the resulting TD analytic Fourier inversion integral can be approximated by rapidly computable closed form expressions. The same approach can be applied to discretizing PO integrals as in (2). One obtains the following approximate pulsed beam (PB) expansion for the reflected field (see Ref. 6 for details)

$$e^r(x, z, t) \sim \sum_{|m| \leq (d/2L)} c_m^r b_m^r(x, z, t - t_m^r), \quad (8)$$

where the Gabor expansion coefficients c_m^r and the time delay t_m^r are approximated by sampling the TD-PO surface current at the lattice points $x_m = mL$,

$$c_m^r = (L/\sqrt{2})^{1/2} g(x_m) \mathcal{R}_0(x_m), \quad t_m = c^{-1} (z_A - z_m - x_m \sin \theta_m^i \cos \theta_m^i), \quad (9)$$

where $z_m = h(x_m)$, $\theta_m^i \equiv \theta^i(x_m)$ is the local incidence angle, and $\mathcal{R}_0(x_m)$ is the local Fresnel reflection coefficient evaluated at the center angular frequency Ω_0 of the pulse. The PB propagator in (8) is given by⁶

$$b_m^r(x, z, t) = \text{Re} \left\{ (-1)^j \beta_m^r \left[\mathcal{T}_m^r \Gamma\left(\frac{3+2j}{4}\right) M_1^{(j)}\left(\frac{t - \tau_m^r}{\mathcal{T}_m^r}\right) - 2i(t - \tau_m^r) \Gamma\left(\frac{5+2j}{4}\right) M_2^{(j)}\left(\frac{t - \tau_m^r}{\mathcal{T}_m^r}\right) \right] \right\}, \quad (10)$$

where

$$\beta_m^r = 2^{j+1/2} \pi^{-1/2} (\mathcal{T}_m^r)^{-j-5/2} \Lambda_m^r \Xi_\zeta T, \quad \Lambda_m^r = -i 2^{5/4} \exp(i\pi/4) c^{-1} \sqrt{\frac{L}{8\pi}} \frac{\zeta_m}{(R_m^r)^{3/2}}, \quad (11)$$

$$\zeta_m = (x - x_m) \sin \theta_m^i + (z - z_m) \cos \theta_m^i, \quad (12)$$

$$\tau_m^r = c^{-1} (R_m^r + x_m \sin \theta_m^i \cos \theta_m^i + T/2), \quad \mathcal{T}_m^r = \frac{L \cos^2 \theta_m^i}{2c\sqrt{2\pi}} \sqrt{1 - \frac{z_{bm}^r}{R_m^r}}, \quad T_m^r = \sqrt{(\mathcal{T}_m^r)^2 + \varsigma^2 T^2}, \quad (13)$$

and (x_{bm}^r, z_{bm}^r) are beam-centered coordinates,

$$\begin{bmatrix} x_{bm}^r \\ z_{bm}^r \end{bmatrix} = \begin{bmatrix} \cos(2\theta_m^i) & -\sin(2\theta_m^i) \\ \sin(2\theta_m^i) & \cos(2\theta_m^i) \end{bmatrix} \begin{bmatrix} x - x_m \\ z - z_m \end{bmatrix}, \quad R_m = [(x_{bm}^r)^2 + (z_{bm}^r)^2]^{1/2}. \quad (14)$$

Moreover, in (10), $\Gamma(\cdot)$ denotes the gamma function,¹⁰ and

$$M_1^{(j)}(t) = {}_1F_1\left(\frac{3+2j}{4}, \frac{1}{2}, -t^2\right), \quad M_2^{(j)}(t) = {}_1F_1\left(\frac{5+2j}{4}, \frac{3}{2}, -t^2\right), \quad (15)$$

with ${}_1F_1(u, v, t)$ denoting the Kummer confluent hypergeometric function.¹⁰ The functions $M_{1,2}^{(j)}$ can be computed efficiently using a rapidly converging power series expansion derived in Ref. 6. The propagator in (10) is a pulsed Gaussian beam, whose collimation is controlled by the discretization period L . The expansion in (8) has been thoroughly calibrated against a rigorous reference solution,⁶ and has been found to provide accurate and robust syntheses for $L \ll d$, i.e., for *narrow-waisted*, poorly collimated PB propagators. The corresponding PB expansion for the transmitted field can be obtained similarly (see Sec. 3.1), as can results for oblique incidence.⁶ Extension to 2D surfaces, and 3D field scattering can be derived based on 2D aperture PB discretization.¹¹

2.3. Surface Estimation

As noted earlier, the proposed *robust* inversion strategy is based on a low-dimensional compact geometrical parameterization of the unknown interface profile, whose unknown parameters are estimated by *fitting* the model-based forward scattering prediction to the available (measured/simulated) data, i.e., minimizing a suitable *cost functional*. The choice of the interface profile parameterization requires tradeoff between compactness and versatility, keeping in mind that the number of unknown parameters N to be estimated must be *smaller* than the collected scattered field data size, i.e., $N \sim N_r \times N_t$. As in Ref. 4, we parameterize the rough surface coarse shape in terms of quartic splines,¹²

$$h(x) \approx \sum_{n=1}^N c_n s_n^{(4)}(x), \quad (16)$$

where c_n are unknown coefficients, and $s_n^{(4)}$ represents a quartic B-spline basis function.¹²

Let $\hat{e}_{pq}^r = \hat{e}^r(x_p^r, z^r, t_q)$ denote the y -directed reflected field *measured* at time t_q at sensor position x_p^r . Given a vector of spline coefficients $\underline{c} = \{c_1, \dots, c_N\}$ and the incident field in (1), we use the PB algorithm in Sec. 2.2 for the surface profile in (16) to generate predictions of the reflected field waveforms at each receiver. Let $e_{pq}^r = e^r(x_p^r, z^r, t_q; \underline{c})$ denote the *model-based prediction* of the reflected field at time t_q at sensor position x_p^r , for surface profile coefficients \underline{c} . Accordingly, we define the cost functional as follows

$$J(\underline{c}) = \|\underline{e}^r(\underline{c}) - \hat{\underline{e}}^r\|^2 = \sum_{p=1}^{N_r} \sum_{q=1}^{N_t} \gamma_p (e_{pq}^r - \hat{e}_{pq}^r)^2, \quad \gamma_p = \left[\max_q \{\hat{e}_{pq}^r\} \right]^{-2}. \quad (17)$$

As in Ref. 4, the *regularized* inverse scattering problem is formalized as finding the coefficient vector \underline{c} in (16) which minimizes the cost functional $J(\underline{c})$ in (17), i.e. finding $\hat{\underline{c}}$ such that

$$\hat{\underline{c}} = \arg \min_{\underline{c}} J(\underline{c}). \quad (18)$$

The cost functional in (18) is generally *non-convex* with respect to \underline{c} , and therefore its optimization requires particular care due to the possible presence of local minima. In the narrow-band frequency range investigated in Ref. 4, it was found that the smoothness of the cost functional was strongly dependent on the frequency content of the excitation field, and the global optimization was achieved via a *continuation method* based on the selected use of the data at the various available frequencies. For the pulsed excitation of interest here, the pulse length cT plays the key role. In particular, to enhance resolution in the reconstruction, the pulse should be as short as possible. However, an exceedingly wide-band excitation would most likely result in a highly non-convex cost functional with many local minima, whose global minimization would be very expensive from the computational viewpoint. Furthermore, for underground imaging, it is also important to operate at sufficiently low frequencies for adequate soil penetration. In our numerical experiments, we found that a suitable trade-off between these contrasting requirements can be actually achieved by using typical wide-band pulses in the GPR frequency range.

2.4. Results

In order to test our surface profile estimation strategy, we generated synthetic field measurement data using a rigorous reference solution of the forward scattering problem (see Ref. 6 for details), with the (fourth-order Rayleigh) wide-band pulse excitation in Fig. 2 (2.45 GHz center frequency) and a cosine-tapered transverse field distribution,

$$g(x) = \begin{cases} \cos(\pi x/d), & |x| \leq d/2, \\ 0, & |x| > d/2, \end{cases} \quad (19)$$

on an aperture of width $d = 1\text{m}$. The chosen excitation, typical of realistic GPR applications, was found to yield relatively smooth cost functionals, whose minimization was performed via the Polak-Ribiere version of the conjugate gradient (CG) algorithm,¹³ assuming as initial guess a flat interface at $z = 0$. A typical reconstruction example is shown in Fig. 3, for the simulation parameters listed in the figure caption. The soil parameters were chosen so as to simulate a class of realistic soils (Puerto Rican clay loam⁹). The surface realization, parameterized in this experiment with 20 B-spline basis functions, was generated randomly so as to mimic typical ($\sim 2 - 3$ cm peak-to-peak) natural roughness. In this experiment, $N_r = 11$ equispaced receivers were used, with $N_t = 100$ time samples, and convergence of the CG minimization was achieved in 20 iterations. As one can see, the reconstruction is reasonably accurate throughout most of the interval, except near the edges of the illumination region. This kind of accuracy was observed in many numerical experiments, with typical overall computing times of 1 min. on a laptop PC.

3. SUBSURFACE IMAGING

Having established the possibility of estimating the coarse shape of the rough air-ground interface, we now turn to the problem of *subsurface imaging* in the presence of a *known* moderately rough interface.

Figure 2. Fourth-order Rayleigh pulse in (7) ($j = 4$, $T = 1.3$ ns, $\Xi = T/30000$, $\varsigma = 1/\sqrt{50}$). (a): Temporal profile; (b): Spectrum (magnitude).

Figure 3. Rough-surface reconstruction example. Soil parameters: $\epsilon_r = 4.5$, $\sigma = 0.012$ S/m. Incident field in (1), with $g(x)$ in (19), and $p(t)$ as in Fig. 2, and with $z_A = 0.2$ m and $d = 1$ m. Collected data: $N_r = 11$ receivers at $z_{obs} = 0.3$ m, equispaced within $[-0.5\text{m}, 0.5\text{m}]$; $N_t = 100$ time samples at each receiver. — True; - - - Reconstruction.

3.1. Forward Scattering Model

We refer to the problem geometry in Fig. 1, but now include a buried target with dielectric permittivity $\epsilon_r^{(tar)}$ and conductivity $\sigma^{(tar)}$ occupying the region $D^{(tar)}$ in the half-space $z < h(x)$. In the frequency domain, the TM-polarized *total* field observed at the receiver location $\mathbf{r}^r = (x^r, z^r)$ can be written as

$$E(\mathbf{r}^r, \omega) = E^b(\mathbf{r}^r, \omega) + E^s(\mathbf{r}^r, \omega), \quad (20)$$

where E^b represents the *background field* (i.e., the field in the absence of the target), and

$$E^s(\mathbf{r}^r, \omega) = \frac{\omega^2}{c^2} \int \int_{D^{(tar)}} G_b(\mathbf{r}^r, \mathbf{r}', \omega) E(\mathbf{r}', \omega) O(\mathbf{r}', \omega) d\mathbf{r}' \quad (21)$$

is the field scattered by the target. In (21), G_b represents the FD Green's function of the rough-interface dielectric half-space, E is the *total* field in the target region, and

$$O(\mathbf{r}', \omega) = [\epsilon_r^{(tar)}(\mathbf{r}') - \epsilon_r] + i \frac{[\sigma^{(tar)}(\mathbf{r}') - \sigma]}{\omega \epsilon_0} = \Delta \epsilon_r(\mathbf{r}') + i \frac{\Delta \sigma(\mathbf{r}')}{\omega \epsilon_0} \quad (22)$$

is referred to as the *object function*. The integration in (21) is limited over the region $D^{(tar)}$ in which the object function is nonzero. For pulsed excitation, with time dependence $p(t)$, by Fourier inversion of (20) and (21) one obtains

$$e(\mathbf{r}^r, t) = e^b(\mathbf{r}^r, t) + e^s(\mathbf{r}^r, t), \quad (23)$$

$$e^s(\mathbf{r}^r, t) = - \int \int_{D^{(tar)}} \left\{ \Delta \epsilon_r(\mathbf{r}') \frac{\partial^2}{\partial t^2} [g_b(\mathbf{r}^r, \mathbf{r}', t) \otimes e(\mathbf{r}', t)] + \frac{\Delta \sigma(\mathbf{r}')}{\epsilon_0} \frac{\partial}{\partial t} [g_b(\mathbf{r}^r, \mathbf{r}', t) \otimes e(\mathbf{r}', t)] \right\} d\mathbf{r}', \quad (24)$$

where g_b represents the space-time Green's function of the rough-interface dielectric half-space (i.e., the Fourier inverse transform of G_b in (21)), e is the *total* field in the target region for pulsed excitation $p(t)$, and \otimes indicates time convolution. Assuming that the rough interface profile is known, one can employ the pulsed beam synthesis in (8) to generate prediction of the *background field* contribution e^b in (23) for a given pulsed excitation, and therefore *isolate* the contribution e^s from the buried target. The relation in (24) between the scattered field at the receivers and the dielectric/conductivity inhomogeneities $\Delta \epsilon$ and $\Delta \sigma$ is *nonlinear*, due to the presence of the total field e which is itself dependent on $\Delta \epsilon$ and $\Delta \sigma$. However, for plastic anti-personnel land mines, of particular interest in our investigation, the dielectric properties of the buried target are typically close to those of the background soil, i.e., $\epsilon_r^{(tar)} \approx \epsilon_r$, $\sigma^{(tar)} \approx 0$; therefore one can resort to approximate linearized approaches valid in the *weak scattering* limit. The simplest such approach is the Born approximation,¹⁴ where one replaces the *total* field e inside the target with the *transmitted* field e^t in the target region, in the absence of the inhomogeneity. For nonconducting targets ($\sigma^{(tar)} \approx 0$, i.e., $\Delta \sigma(\mathbf{r}') \approx 0$), this yields a *linear* model relating the scattered field at the receivers to the dielectric inhomogeneity $\Delta \epsilon_r$,

$$e^s(\mathbf{r}^r, t) \approx - \int \int_{D^{(tar)}} \left\{ \Delta \epsilon_r(\mathbf{r}') \frac{\partial^2}{\partial t^2} [g_b(\mathbf{r}^r, \mathbf{r}', t) \otimes e^t(\mathbf{r}', t)] + \frac{\sigma}{\epsilon_0} \frac{\partial}{\partial t} [g_b(\mathbf{r}^r, \mathbf{r}', t) \otimes e^t(\mathbf{r}', t)] \right\} d\mathbf{r}'. \quad (25)$$

The limitations of this approximation, which neglects multibounce interactions inside the target, have been thoroughly investigated and are well documented in the technical literature (see, e.g., Ref. 15). Moreover, more sophisticated and accurate *nonlinear* versions have been proposed (see, e.g., Refs. 16,17).

To implement the linear model in (25) for a given pulsed excitation, one needs to compute the transmitted field e^t in the target region (in the absence of the target), and the space-time Green's function g_b of the soil. As shown in Sec. 2.2, the computation of the field transmitted through moderately rough dielectric interfaces can be carried out efficiently through the PB algorithm in Ref. 6. The transmitted field PB synthesis is formally analogous to that in (8)–(14) for the reflected field. One obtains (see Ref. 6 for details)

$$e^t(x, z, t) \sim \sum_{|m| \leq (d/2L)} c_m^t b_m^t(x, z, t - t_m^t), \quad (26)$$

with

$$b_m^t(x, z, t) = \text{Re} \left\{ (-1)^j \beta_m^t \left[\mathcal{T}_m^t \Gamma \left(\frac{3+2j}{4} \right) M_1^{(j)} \left(\frac{t - \tau_m^t}{\mathcal{T}_m^t} \right) - 2i(t - \tau_m^t) \Gamma \left(\frac{5+2j}{4} \right) M_2^{(j)} \left(\frac{t - \tau_m^t}{\mathcal{T}_m^t} \right) \right] \right\}, \quad (27)$$

where

$$\beta_m^t = 2^{j+1/2} \pi^{-1/2} (\mathcal{T}_m^t)^{-j-5/2} \Lambda_m^t \Xi_\zeta T, \quad \tau_m^t = c^{-1} [\sqrt{\epsilon_r} (R_{m0}^t + x_m \sin \theta_{m0}^R \cos \alpha_m) + T/2], \quad (28)$$

$$\Lambda_m^t = i(\epsilon_r)^{1/4} 2^{5/4} \exp(-\kappa R_{m0}^t + i\pi/4) c^{-1} \sqrt{\frac{L}{8\pi}} \frac{\zeta_m}{(R_{m0}^t)^{3/2}}, \quad \kappa = \frac{\sigma}{2c\epsilon_0 \sqrt{\epsilon_r}}, \quad (29)$$

$$T_m^t = \sqrt{\epsilon_r} \frac{L \cos \alpha_m \cos \theta_{m0}^R}{2c\sqrt{2\pi}} \sqrt{1 - \frac{z_{bm0}^t}{R_{m0}^t}}, \quad \mathcal{T}_m^t = \sqrt{(T_m^t)^2 + \zeta^2 T^2}, \quad (30)$$

$$R_{m0}^t = \sqrt{(x_{m0}^t)^2 + (z_{m0}^t)^2}, \quad \begin{bmatrix} x_{bm0}^t \\ z_{bm0}^t \end{bmatrix} = \begin{bmatrix} \cos \gamma_{m0}^t & \sin \gamma_{m0}^t \\ \sin \gamma_{m0}^t & -\cos \gamma_{m0}^t \end{bmatrix} \begin{bmatrix} x - x_m \\ z - h(x_m) \end{bmatrix}, \quad (31)$$

$$\theta_{m0}^R \equiv \sin^{-1} (\sin \theta_m^i / \sqrt{\epsilon_r}), \quad \gamma_{m0}^t = \theta_{m0}^R + \alpha_m. \quad (32)$$

Figure 4 shows a typical transmitted field waveform, for the excitation and specified rough surface geometry in Fig. 3, computed via the PB synthesis in (26)–(32) (with 50 beams) and via the rigorous reference solution detailed in Ref. 6. As for the reflected field, the PB synthesis provides a robust, fast and reasonably accurate approximation for the transmitted field, which can be fruitfully exploited for efficient implementation of (25).

The computation of the space-time Green's function g_b for the rough-interface dielectric half-space geometry could be accomplished by generalizing the transmitted field PB synthesis in (26)–(32) to the case of cylindrical incident wavefronts and impulsive time excitation. However, for the present, we are interested in a more efficient approach to the PB expansion of the *whole* convolution $g_b \otimes e^t$ and its time derivatives in (25). This approach, now under investigation, involves more cumbersome algebra, but would substantially increase the computational efficiency, avoiding the time-consuming numerical convolution.

3.2. Subsurface Reconstruction

We now discuss how to use the forward scattering model to invert GPR data and generate estimates of the subsurface property distribution – i.e. how to do imaging. Such an inversion scheme can be constructed by discretizing the test domain $D^{(test)}$ to be imaged into a number of adequately small pixels and relating these values to the observations of the scattered field waveforms at the receivers through the linear forward scattering model in (25). Assuming that N_t time samples of the scattered field e^s are collected at N_r receivers, and that the test domain is discretized into N_p pixels, the forward model in (25) can be discretized accordingly and cast into matrix form as:

$$\underline{y} = \underline{A} \cdot \underline{x} + \underline{n}, \quad (33)$$

where \underline{y} is a column vector containing the $N_r \cdot N_t$ time samples of the *known term* in (25),

$$e^s(\mathbf{r}^r, t) + \frac{\sigma}{\epsilon_0} \int \int_{D^{(test)}} \frac{\partial}{\partial t} [g_b(\mathbf{r}^r, \mathbf{r}', t) \otimes e^t(\mathbf{r}', t)] d\mathbf{r}', \quad (34)$$

\underline{x} is a N_p -element column vector containing the *unknown* dielectric contrast $\Delta\epsilon_r$ at each pixel, \underline{A} is a $(N_r \cdot N_t) \times N_p$ matrix containing the space-time discretization of the integral

$$- \int \int_{D^{(test)}} \frac{\partial^2}{\partial t^2} [g_b(\mathbf{r}^r, \mathbf{r}', t) \otimes e^t(\mathbf{r}', t)] d\mathbf{r}', \quad (35)$$

Figure 4. Parameters as in Fig. 3. Transmitted field through the true rough interface profile observed at $x = 0$, $z = -0.1\text{m}$. — Reference solution; - - - PB synthesis in (26)–(32) (50 beams).

and the *noise* vector \underline{n} accounts for measurement uncertainty and unmodeled small scale *clutter*. Due to the inherent ill-posedness of this inverse scattering problem, and the various approximations in our model, the reconstruction *cannot* be simply accomplished via the (pseudo-)inverse of the matrix \underline{A} . In order to obtain reasonably accurate reconstructions, it is essential to incorporate stabilization steps, known as regularization. In a number of recent investigations restricted to flat air-ground interfaces,^{18,19} we have explored various *object-based* regularization approaches, such as *total variation*¹⁸ and *curve evolution*,¹⁹ which have been found to provide quite accurate and robust reconstructions. We are currently working on extending these approaches to the more challenging case of rough interfaces.

4. CONCLUSIONS

We have presented an approach for imaging objects buried under a rough air/soil interface from ground penetrating radar data. Our approach is based on estimation of the rough surface followed by subsurface imaging. We have a Gaussian-beam approximate physical model for the scattering problem that is efficient and well matched to the estimation/inversion problem. This model was demonstrated for the problem of surface profile estimation. We presented an approach to the subsequent subsurface estimation problem based on an approximate Greens function for the subsurface scattering.

We are currently pursuing several extensions to the present work. We are considering extensions to include sensor fusion, particularly using sensors which provide surface information such as optical range sensors. This information would improve the surface estimates, and allow for more accurate isolation of subsurface scattering signals. We are also extending our models to represent two different physical GPR systems for which we have experimental data: a downward-looking GPR array and a forward-looking GPR array. Once these models are complete, we will evaluate their performance on the collected GPR data.

Abstract: For one-dimensional aperture excitations, a two-dimensional Gabor-based Gaussian beam (GB) algorithm is presented which describes field scattering by, and transmission through, a moderately rough interface between two dielectric media. The proposed algorithm extends the results in Maciel and Felsen[1], and is shown to produce accurate and computationally efficient solutions for this complex propagation environment, over a range of calibrated combinations of the problem parameters.

INTRODUCTION AND PROBLEM FORMULATION

Gabor-based Gaussian beam (GB) algorithms, in conjunction with the complex source point (CSP) method for generating beam-like wave objects, have found application in a variety of high frequency wave propagation and diffraction scenarios. Of special interest for efficient numerical implementation is the non-collimated narrow-waisted species of GB which reduces the computationally intensive complex ray tracing for collimated GB propagation and scattering to quasi-real ray tracing, without the failure of strictly real ray field algorithms in caustic and other transition regions. The Gabor-based narrow-waisted CSP-GB method has been applied previously (Maciel and Felsen[1]) to two-dimensional (2D) propagation from extended nonfocused and focused aperture distributions through arbitrarily curved 2D layered environments. In the present 2D study, the method is applied to 1D-aperture-excited field scattering from, and transmission through, a moderately rough interface between two dielectric media, as depicted in Fig. 1. In the 2D coordinate space (x, z) , a y -directed electric field with time-harmonic dependence $\exp(-i\omega t)$ and spatial distribution $f(x)$ is assumed to occupy the aperture region $|x| \leq d/2$ at $z = z_A$ in free space, i.e., $E^{inc}(x, z_A) = f(x), |x| \leq d/2$; $E^{inc}(x, z_A) = 0, |x| > d/2$. The aperture-radiated field illuminates a homogeneous dielectric half-space, with relative permittivity ϵ_r , bounded by a moderately rough (both in height and slope) interface described by a continuous function $z = h(x)$. Our ultimate goal is to develop an efficient forward scattering solver for inverse problems concerned with profile and object reconstruction (Galdi et al.[2]).

GABOR-BASED GAUSSIAN BEAM DISCRETIZATION

Aperture-Radiated Field. The Gabor-based CSP-GBs are generated by Gaussian initial fields in the x -domain ($z = z_A$) aperture plane. The initial fields are centered on a discretized Gabor lattice in the (x, k_x) phase space indexed by (x_m, k_{xn}) , with $(m, n) = 0, \pm 1, \pm 2, \dots$, where k_x is the x -domain spectral wavenumber; L_x and β_x denote the spatial and spectral lattice periods, respectively, subject to the constraint $L_x \beta_x = 2\pi$. Thus, m tags the spatial displacement $x_m = mL_x$, while n tags the spectral displacement (tilt) $k_{xn} = n\beta_x$ of the Gabor-GBs. As

The work of V. Galdi was also supported by a European Union postdoctoral fellowship through the University of Sannio, Benevento, Italy. L.B. Felsen also acknowledges partial support from Grant No. 9900448 by the US-Israel Binational Science Foundation, Jerusalem, Israel, and from Polytechnic University, Brooklyn, NY 11201, USA.

shown in Maciel and Felsen[1], for narrow-waisted (NW) GBs with $L_x \leq \lambda_0 \ll d$, λ_0 being the free-space wavelength, the $n \neq 0$ tilted GBs are *evanescent* (i.e, non-contributing) sufficiently far from the $z = z_A$ plane. Coupled with high frequency asymptotics, this property allows the conventional computationally intensive determination of the exact excitation amplitudes due to a Gabor-discretized large aperture distribution to be avoided and replaced with adequate accuracy by sampling the aperture profile at the x_m lattice point locations (Maciel and Felsen[1]). Field synthesis at the observer is accomplished by adding contributions from the ray-like $n = 0$ nontilted NW-CSP-GBs. The incident field is thus written as (Galdi et al.[3])

$$E^{inc}(x, z) \approx \sum_{|m| \leq L_x/2d} A_m B_m(x, z), \quad A_m = \left(L_x/\sqrt{2}\right)^{1/2} f(x_m), \quad (1)$$

where the CSP beam propagator B_m is given by

$$B_m(x, z) \sim ik_0 2^{5/4} \left(\frac{L_x}{8\pi k_0 \tilde{R}_m} \right)^{1/2} \exp \left\{ i \left[k_0 (\tilde{R}_m + ib) + \pi/4 \right] \right\} \frac{(z + ib)}{\tilde{R}_m}, \quad (2)$$

with $k_0 = 2\pi/\lambda_0$ being the free-space wavenumber, $\tilde{R}_m = \left[(x - x_m)^2 + (z + ib)^2 \right]^{1/2}$ (with $\Re(\tilde{R}_m) \geq 0$) denoting the *complex distance* between the observation point (x, z) and the CSP $(x_m, -ib)$, and $b = L_x^2/\lambda_0$ representing the Fresnel length of the beam. Here and henceforth, the tilde \sim identifies CSP complex quantities.

Reflected and Transmitted Fields. In the presence of the rough dielectric interface environment, the NW-GBs launched from the aperture plane can be tracked like *quasi-real* rays, as shown in Maciel and Felsen[1]. We begin with the canonical problem of CSP Gaussian beam reflection from a curved segment of a dielectric boundary, as depicted in Fig. 2, which furnishes the building-blocks for the rough surface scattering algorithm (whose complete description can be found in Galdi et al.[3]). Referring to Fig. 2, an incident Gaussian beam is generated by a CSP at $\tilde{P}_s \equiv (x_s + ib \cos \alpha_s, z_s + ib \sin \alpha_s)$, α_s being the real departure angle of the beam axis relative to the x -axis. For electrically large and smooth scatterers, and when the observation point $P \equiv (x, z)$ lies in the paraxial region of a reflected beam, the reflected field can be approximated in terms of the on-axis field of that beam (i.e., a *real* ray) and a complex phase correction (Maciel and Felsen[1]). Denoting the on-axis parameters by the subscript zero, one finds (Galdi et al.[3])

$$E^{refl}(P) \approx E^{refl}(P_0) \Big|_{\tilde{P}_i = P_{i0}} \exp(ik_0 \tilde{\delta}_p) = \Gamma E^{inc}(P_{i0}) \left(\frac{\tilde{f}_{r0}}{\tilde{R}_0} \right)^{1/2} \exp \left[ik_0 (L_{r0} + \tilde{\delta}_p) \right]. \quad (3)$$

Here (see Fig. 2): $\tilde{R}_0 = \overline{F_{r0} P_0}$; $\tilde{R} = \overline{F_{r0} P}$; $\tilde{L}_{i0} = \overline{\tilde{P}_s P_{i0}}$; $L_{r0} = \overline{P_{i0} P_0}$; $\tilde{\delta}_p = \tilde{R} - \tilde{R}_0$ is the complex phase correction; $\tilde{F}_{r0} = (x_{i0} - \tilde{f}_{r0} \cos \alpha_r, z_{i0} - \tilde{f}_{r0} \sin \alpha_r)$ is the *complex* (virtual) focus obtained by analytic continuation of the standard ray-optical formulas, with $\tilde{f}_{r0} = \tilde{L}_{i0} r_c \cos \theta_i / (2\tilde{L}_{i0} + r_c \cos \theta_i)$; the complex incidence point \tilde{P}_i is approximated by the real beam-axis incidence point $P_{i0} \equiv (x_{i0}, z_{i0})$; α_r is the real departure angle of the reflected beam axis relative to the x -axis; r_c is the curvature radius at P_{i0} ; and Γ is the relevant TM plane-wave Fresnel reflection coefficient. As shown in (Maciel and Felsen[1]), this corresponds to tracing a ray along a *complex* trajectory from the CSP to the intersection of the *real* beam axis with the real surface; from there the path to the observer proceeds entirely in real configuration space, along the beam axis. Transmitted fields and possible multiple interactions can be modeled in a similar fashion (see Galdi et al.[3] for details).

RESULTS AND CONCLUSIONS

From an extensive set of reflected/transmitted field examples for different choices of problem parameters, calibrating each through comparison with an independent numerical reference solution (Galdi et al.[3], Leviatan and Boag[4]), we have chosen the lossy interface profile $h(x)$ in Fig. 3, excited by a nonphased cosine aperture field distribution ($f(x) = \cos(\pi x/d)$) of width $d = 80\lambda_0$, located at $z_A = 6.4\lambda_0$ on the height scale of Fig. 3, i.e., very close to the maximum profile height of $6\lambda_0$. The Fresnel zone reflected field observed at $z_{or} = 20\lambda_0$ is shown in Fig. 4. Here, $L_x = d/80 = \lambda_0$. On the plot, the beam-generated solution (dashed) agrees very well with the reference solution (solid) in this typical example. In our numerical experiments, we have found accurate results for moderate roughness with maximum slopes $\leq 40^\circ$ and (average) curvature radii larger than a wavelength, and for incidence directions far from grazing, with typical computing times of about 9 ms per point on a 500 MHz laptop. These results suggest that our algorithm is promising as a fast forward solver in complex wave scattering scenarios.

Abstract: In this paper, we present a computationally efficient and physically appealing discretized Gabor-based algorithm constructed with *narrow-waisted* ray-like pulsed Gaussian beams, for the two-dimensional (2D) electromagnetic fields radiated from short-pulsed large 1D truncated aperture distributions. This analysis extends the time-harmonic results in Maciel and Felsen[1] to the time domain.

INTRODUCTION AND PROBLEM FORMULATION

Narrow-waisted, ray-like, Gabor-based Gaussian beam (GB) algorithms have been shown capable of providing robust and efficient syntheses for radiation from finite one-dimensional (1D) aperture distributions (Maciel and Felsen[1]) and the interaction of these 2D fields with complex 2D environments (Maciel and Felsen[2], Galdi et al.[3]). The investigations have been restricted to time-harmonic excitation, whereby the complex source point (CSP) method can be exploited effectively for tracking each basis beam. Here, we present the extension of the frequency domain (FD) results for aperture radiation in Maciel and Felsen[1] to short-pulse time-dependent (TD) excitation. Referring to the problem geometry in Fig. 1, we consider a 1D (y -directed) space-time aperture field distribution of width d at $z = 0$, with separable space-time dependence and linear time delay

$$e_y(x, z=0, t) = f(x, t), |x| \leq d/2, \quad f(x, t) = g(x) p(t - c^{-1}x \sin \theta_A), \quad (1)$$

where c is the speed of the light and $p(t)$ is a pulse with characteristic width $T_p \ll d/c$. This distribution gives rise to a space-time pulse propagating in the θ_A direction (see Fig. 1). The FD algorithm in Maciel and Felsen[1] evolves from the rigorous Kirchhoff integration over the aperture distribution, which is then parameterized via the discrete Gabor basis and evaluated asymptotically for high frequencies to furnish the GB propagators to the observer. The TD results here are obtained by Fourier inversion from the FD and yield pulsed beams (PB).

NARROW-WAISTED GAUSSIAN BEAM DISCRETIZATION

Frequency Domain. In the 2D domain (x, z) , the high-frequency narrow-waisted (NW) basis beams are excited by Gaussian initial field profiles which, in the 1D aperture plane $z = 0$, are centered on the Gabor lattice points $x_m = mL_x$, $k_{xm} = n\beta_x$, with $(m, n) = 0, \pm 1, \pm 2, \dots$, in the (x, k_x) phase space (k_x is the x -domain spectral wavenumber). The spatial and spectral periods L_x and β_x , respectively, are constrained by $L_x\beta_x = 2\pi$. For NW beams with $L_x \ll d$, the spectral displacement (tilt) $\beta_x = 2\pi/L_x \gg 1$, thereby making the $n \neq 0$ basis beams evanescent and therefore negligible “sufficiently far” from the aperture plane (Maciel and Felsen[1]). By high frequency asymptotics, the NW-GB propagators can be modeled via the complex-source-point (CSP)

method, with their excitation amplitudes determined approximately from sampling of the aperture profile at the spatial lattice points x_m . Accordingly, for time-harmonic $\exp(-i\omega t)$ excitation, the radiated field can be represented by beam superposition as (Galdi et al.[4]),

$$E_y(x, z, \omega) \approx \sum_{|m| \leq d/2L_x} C_m B_m(x, z, \omega), \quad C_m = \left(L_x / \sqrt{2}\right)^{1/2} g(x_m), \quad (2)$$

$$B_m(x, z, \omega) \sim -ik 2^{5/4} \left(\frac{L_x}{8\pi}\right)^{1/2} \exp\left\{i\left[k\left(\tilde{R}_m + x_m \sin\theta_A + ib\right) + \pi/4\right]\right\} \frac{(z - ib \cos\theta_A)}{\tilde{R}_m^{3/2}}. \quad (3)$$

Here, $k = \omega/c = 2\pi/\lambda$ is the ambient wavenumber with λ as the wavelength, $\tilde{P}_m \equiv (x_m + ib \sin\theta_A, ib \cos\theta_A)$ is the CSP, the complex displacement magnitude $b = (L_x \cos\theta_A)^2 / \lambda$ is the Fresnel length of the beam, and $\tilde{R}_m = \left[(x - x_m - ib \sin\theta_A)^2 + (z - ib \cos\theta_A)^2\right]^{1/2}$ (with $\Re(\tilde{R}_m) \geq 0$), is a *complex distance*; through $L_x = 2\pi/\beta_x$, C_m is λ -dependent.

Time Domain. When Fourier-inverting to the short-pulse TD to generate pulsed beams, we choose L_x to be λ -independent because this renders the aperture-sampled TD-Gabor PB-excitation coefficients λ -independent. Specifically, via the analytic signal formulation (one-sided Fourier transform), one has (Galdi et al.[4]),

$$e_y(x, z, t) \approx \sum_{|m| \leq d/2L_x} c_m b_m(x, z, t), \quad c_m = \left(L_x / \sqrt{2}\right)^{1/2} g(x_m), \quad (4)$$

$$b_m(x, z, t) = \Re e \left[\frac{1}{\pi} \int_0^\infty B_m(x, z, \omega) P(\omega) \exp(-i\omega t) d\omega \right], \quad (5)$$

where $P(\omega)$ represents the spectrum of the pulse $p(t)$. We then find that, subject to certain constraints which are validated subsequently by numerical experimentations, the approximate inversion integrals in (5) for Gaussian-envelope-modulated pulses can be evaluated in closed form in terms of efficiently computable hypergeometric functions (Galdi et al.[4]). The constraints are formalized through nondimensional critical estimators which contain all relevant problem parameters, and show how changes in one parameter can be compensated by corresponding changes in the other parameters so as to remain in the legitimized range. The results can be generalized to arbitrarily phased (e.g., focused) aperture distributions (Galdi et al.[4]).

RESULTS AND CONCLUSIONS

For illustration, we consider a non-phased (i.e., $\theta_A = 0$) cosine-tapered distribution with a fourth-order Rayleigh pulse excitation,

$$g(x) = \cos(\pi x/d), \quad p(t) = \left(\frac{T_p^4}{30000}\right) \frac{d^4}{dt^4} \exp\left[-\frac{50(t - T_p/2)}{T_p^2}\right]. \quad (6)$$

Figure 2 shows typical temporal and spatial profiles, computed via the PB algorithm (dashed curves) and a reference solution obtained by rigorous space-time Kirchhoff aperture numerical integration (solid curves). The two results coincide on the scale of the drawings. The same type of agreement is observed for more complex (phased, focused) aperture field distributions (Galdi et al.[4]). These results confirm that the previously established utility of the Gabor-based narrow-waisted FD-GB algorithm for radiation from distributed apertures in Maciel and Felsen[1] remains intact in the TD. In the FD, it has been established that the GB basis beams can be tracked efficiently from the aperture through interactions with complex scattering environments (Maciel and

Felsen[2]), and are therefore useful forward solvers in inversion scenarios (Galdi et al.[5]). Interaction of the PB propagators with complex environments is presently under consideration (Galdi et al.[6]).

Abstract: In this paper, we present a new technique for determining the surface profile of a one-dimensional moderately rough interface between air and a homogeneous dielectric half space. Based on sparsely sampled step-frequency ground penetrating radar measurements, the proposed inversion scheme uses a quasi-ray Gaussian beam fast forward model, coupled with a low-order parameterization of the surface profile in terms of B-splines. The profile estimation problem is posed as a parameter optimization problem, which is solved using a multiresolution continuation method. Numerical experiments establish that the algorithm is efficient, and computes very accurate profiles throughout most of the illuminated region even in noisy environments, losing accuracy only in regions with very weak illumination.

INTRODUCTION AND PROBLEM FORMULATION

Estimation of rough surfaces from inverse scattering has received considerable attention in the past decade. However, most of the available algorithms have focused on conducting surfaces. Wombell and DeSanto[1] used Kirchhoff approximations and Fourier transforms to estimate surface profiles based on measurements of the scattered field in all spectral directions. Ying and Noguchi[2] used nonlinear optimization techniques for direct estimation of surfaces illuminated by monochromatic Gaussian beams, based on the far-field scattering amplitude for all spectral directions. In a different approach, Schatzberg and Devaney[3] used Rytov approximation and backpropagation to estimate surface profiles based on full measurements of the scattered wave. In contrast with the above contributions, our work in this paper is focused on estimating surface profiles based on reflection from a moderately rough interface between air and a homogeneous dielectric half space (soil). The problem geometry is illustrated in Fig. 1: in a y -independent (x, z) coordinate system, a y -directed field generated by an aperture field distribution at $z = z_A$, $E^{inc}(x, z_A) = f(x)$, $|x| \leq d/2$, is assumed to illuminate a homogeneous dielectric half-space, with known relative permittivity ϵ_r , bounded by an irregular interface described by the continuous function $z = h(x)$. We assume that the reflected field is measured at N_r receivers with discrete spatial locations (x_1, \dots, x_{N_r}) at $z = z_{obs}$, using a stepped-frequency ground penetrating radar (GPR) with N_λ operating wavelengths (frequencies).

ALGORITHMIC ASPECTS

Surface Parameterization. The proposed inversion strategy is based on a low-dimensional compact geometrical parameterization of the unknown interface profile, whose unknown parameters are estimated by fitting the model-based forward scattering prediction to the available (measured/simulated) data, i.e., minimizing a suitable cost functional. The choice of the interface profile parameterization is a key issue, and requires tradeoff between

The work of V. Galdi was also supported by a European Union postdoctoral fellowship through the University of Sannio, Benevento, Italy. L.B. Felsen also acknowledges partial support from Grant No. 9900448 by the US-Israel Binational Science Foundation, Jerusalem, Israel, and from Polytechnic University, Brooklyn, NY 11201, USA.

compactness and versatility. We assume that the surface shape can be approximated by a finite set of quartic B-spline basis functions with unknown coefficients,

$$h(x) \approx \sum_{n=1}^N c_n s_n^{(4)}(x), \quad (1)$$

where $s_n^{(4)}$ indicates a quartic B-spline basis function.

Forward Scattering Model. We exploit a computationally efficient forward model relating the reflected field at the receivers to the surface profile. This model, detailed in Galdi et al.[4], utilizes Gabor-based Gaussian beam algorithms in conjunction with the complex source point (CSP) method for generating beam-like wave objects (Maciel and Felsen[5]). The algorithm has previously been validated and calibrated for the range of parameters involved in this inverse scattering scenario.

Surface Estimation. The surface estimation problem is posed as a nonlinear optimization problem, similar in spirit to the work of Ying and Noguchi[2]. Let $\mathcal{E}_{p,q}^r$ denote the y -directed reflected field measured at wavelength λ_q at sensor position x_p . Given a vector of spline coefficients $\underline{c} = \{c_1, \dots, c_N\}$ and the aperture-excited incident field, we can use the above beam algorithm for the surface profile in (1) to generate predictions of the reflected field waveforms at each receiver, i.e., $E_{p,q}^r \equiv E^r(x_p, z_{obs}; \lambda_q; \underline{c})$. Accordingly, we define the error functional as follows

$$\Phi(\underline{c}) \equiv \left\| \underline{E}^r(\underline{c}) - \underline{\mathcal{E}}^r \right\|^2, \quad (2)$$

where $\underline{E}^r(\underline{c}) = \{E_{p,q}^r\}$, $\underline{\mathcal{E}}^r = \{\mathcal{E}_{p,q}^r\}$, $p = 1, \dots, N_r$, $q = 1, \dots, N_\lambda$. The measured data are simulated via the multifilament current method (Galdi et al.[4], Leviatan and Boag[6]). The regularized inverse scattering is formalized as finding the coefficient vector $\underline{c} = \{c_1, \dots, c_N\}$ in (1) which minimizes the cost functional in (2), i.e. finding $\hat{\underline{c}}$ such that

$$\hat{\underline{c}} = \arg \min_{\underline{c}} \Phi(\underline{c}). \quad (3)$$

We show that this optimization problem has local minima, and develop a multiresolution continuation strategy based on selective use of temporal frequency information to approach convergence to globally optimal estimates of surface profiles (see Galdi et al.[4] for details).

RESULTS AND CONCLUSIONS

From an extensive set of numerical experiments for a broad range of problem parameters, we have chosen the typical reconstruction example in Fig. 2. The surface and soil parameters are specified in the figure caption. The incident field is generated by a cosine-tapered aperture field distribution (i.e., $f(x) = \cos(\pi x/d)$) of width $d = 0.8$ located at $z_A = 0.6$. The complex reflected field is measured at 10 equispaced observation points at $z_{obs} = 0.6$ spanning the illuminated region, and at four operating wavelengths ($\lambda = 0.2, 0.1, 0.067, 0.05$). The length scales are normalized with respect to the smallest radius of curvature of the local interface profile maxima. The multiresolution optimization strategy detailed in Galdi et al.[4] is exploited to minimize the obtained cost functional.

It can be observed that, with the exception of the poorly illuminated edge regions, the reconstruction is reasonably accurate. This kind of accuracy was confirmed in other numerical experiments, even in noisy environments, with computing time of 1-2 minutes on a 400 MHz laptop (Galdi et al.[4]). We are currently working on extending the algorithm to short-pulse excitation (Pavlovich et al.[7]).

I. INTRODUCTION AND PROBLEM FORMULATION

In this paper, we present a computationally efficient and physically appealing discretized Gabor-based parameterization, in terms of *narrow-waisted* ray-like pulsed Gaussian beams, for the three-dimensional (3D) vector electromagnetic fields radiated from short-pulsed arbitrarily polarized large 2D truncated aperture distributions. This analysis extends the time-harmonic results in [1] to the time domain (TD), following the guidelines of our previous investigation of pulsed radiation of 2D fields from 1D large truncated apertures [2].

Referring to the problem geometry in Fig. 1, a 2D space-time aperture field distribution

$$\mathbf{e}_0(x, y, z = 0, t) = \mathbf{f}(x, y, t), \quad (x, y) \in \Gamma_A, \quad \mathbf{u}_z \cdot \mathbf{f} = 0, \quad (1)$$

is assumed to occupy the aperture region Γ_A (of typical dimension d_A) in the $z = 0$ plane. Here and henceforth, bold face symbols denote vector quantities, \mathbf{u}_α denotes a unit vector in the α -direction, and the subscript “0” identifies quantities in the $z = 0$ plane. The resulting space-time field radiated into the half-space $z > 0$ can be rigorously synthesized by Kirchhoff integration [3, p. 175],

$$\mathbf{e}(\mathbf{r}, t) = -\frac{1}{2\pi} \iint_{-\infty}^{\infty} (\mathbf{r} - \mathbf{r}') \times \left\{ \mathbf{u}_z \times \left[\frac{\mathbf{f}(x, y, t - R/c)}{R^3} + \frac{1}{cR^2} \frac{\partial}{\partial t} \mathbf{f}(x, y, t - R/c) \right] \right\} dx' dy', \quad (2)$$

where $\mathbf{r} = x\mathbf{u}_x + y\mathbf{u}_y + z\mathbf{u}_z$, $\mathbf{r}'_0 = x'\mathbf{u}_x + y'\mathbf{u}_y$, $R = |\mathbf{r} - \mathbf{r}'_0|$, and c is the ambient propagation speed. In what follows, we shall be dealing with the simple case of space-time separable aperture fields having linear time delay,

*Work supported by ODDR&E under MURI grants ARO DAAG55-97-1-0013 and AFOSR F49620-96-1-0028, and by the Engineering Research Centers Program of the National Science Foundation under award number EEC-9986821. The work of V. Galdi was also supported by a European Union postdoctoral fellowship through the University of Sannio, Benevento, Italy. L.B. Felsen also acknowledges partial support from a Grant by the US-Israel Binational Science Foundation, Jerusalem, Israel, and from Polytechnic University.

$$\mathbf{f}(x, y, t) = \mathbf{g}(x, y)p[t - c^{-1} \sin \theta_A(x \cos \phi_A + y \sin \phi_A)], \quad (3)$$

with spectrum (capital letters identify frequency domain quantities),

$$\mathbf{F}(x, y, \omega) = P(\omega)\mathbf{g}(x, y) \exp[ik \sin \theta_A(x \cos \phi_A + y \sin \phi_A)], \quad (4)$$

where $p(t)$ is a short pulse of length $T \ll d_A/c$ with spectrum $P(\omega)$. Due to space limitations, we omit the technical details and concentrate on presenting the main results. The interested reader is referred to [4] for a comprehensive treatment.

II. FREQUENCY DOMAIN BEAM DISCRETIZATION

We first recall relevant results of our previous frequency domain (FD) investigation in [1], before proceeding to their inversion (via analytic signal transform) into the time domain. For an implied $\exp(-i\omega t)$ dependence, the FD counterpart of (2) for the radiated 3D field, using the linearly-phased aperture distribution in (4), is given by [3, p. 107]

$$\mathbf{E}(\mathbf{r}) = 2 \int_{-\infty}^{\infty} \nabla G_{3D}(\mathbf{r}, \mathbf{r}'_0) \times [\mathbf{u}_z \times \mathbf{F}(x', y')] dx' dy', \quad (5)$$

where $G_{3D}(\mathbf{r}, \mathbf{r}'_0) = \exp(ikR)/(4\pi R)$ is the 3D-FD Green's function with $k = \omega/c = 2\pi/\lambda$ as the ambient wavenumber, and λ as the wavelength. As shown in [1], [4], the radiated field in (5) can be parameterized effectively in terms of Gabor-based *narrow-waisted complex source point* (CSP) Gaussian beams

$$\tilde{\mathbf{E}}(\mathbf{r}) \sim \sum_{m,p} (\mathbf{C}_{mp} \times \mathbf{u}_z) \times \tilde{\mathcal{B}}_{mp}(\mathbf{r}), \quad \mathbf{C}_{mp} = (L/\sqrt{2})\mathbf{g}(mL, pL), \quad (6)$$

$$\tilde{\mathcal{B}}_{mp}(\mathbf{r}) = ikL \frac{\exp[ik(\tilde{R}_{mp} + ib + \mathcal{L}_{mp})]}{\sqrt{2\pi}\tilde{R}_{mp}^2} (\mathbf{r} - \tilde{\mathbf{r}}'_{mp}), \quad \tilde{R}_{mp} = |\mathbf{r} - \tilde{\mathbf{r}}'_{mp}|, \quad (7)$$

$$\tilde{\mathbf{r}}'_{mp} = (mL + ib \sin \theta_A \cos \phi_A)\mathbf{u}_x + (pL + ib \sin \theta_A \sin \phi_A)\mathbf{u}_y + ib \cos \theta_A \mathbf{u}_z, \quad (8)$$

$$\mathcal{L}_{mp} = L \sin \theta_A (m \cos \phi_A + p \sin \phi_A), \quad b = (L \cos \theta_A)^2/\lambda, \quad (9)$$

where $\tilde{\mathbf{r}}'_{mp}$ is the CSP at the (m, p) -indexed (x, y) plane lattice point, \mathbf{C}_{mp} are Gabor expansion coefficients (obtained by aperture profile sampling), and $\tilde{\mathcal{B}}_{mp}$ is the *ray-like* GB propagator in the (θ_A, ϕ_A) direction, obtained from the 3D-FD Green's function by analytic continuation of the spatial coordinates into complex space (see (8)). The expansion in (6) is a high frequency asymptotic ray-like approximation of the rigorous, Gabor-based, Gaussian beam (GB) discretization presented in [1], which is tied to a discretized lattice in a four-dimensional $(x, y; k_x, k_y)$ space-spectrum phase space, where k_x, k_y are the spectral wavenumbers. Equation (6) has been found to yield accurate syntheses for sufficiently small values of the spatial lattice period $L \lesssim \lambda \ll d_A$, i.e., for narrow-waisted beams. In (6)–(8), the tilde \sim identifies dependence on analytically continued CSP coordinates as well as the field produced thereby. Due to the finite extent of the aperture, i.e., $\mathbf{g}(x, y) = 0$ for $(x, y) \notin \Gamma_A$, the summation in (6) is *self-truncating* up to a number of beams given roughly by $(d_A/L)^2$.

III. TIME DOMAIN BEAM DISCRETIZATION

The corresponding pulsed beam (PB) expansion for the field radiated by the space-time aperture distribution in (3) can be formally obtained by Fourier inversion of (6) filtered by the pulse spectrum $P(\omega)$. Although this cannot be accomplished analytically for the most general pulse shape, we have found rapidly computable closed form approximations for the important class of Rayleigh pulses

$$p(t) = \Xi p_g^{(j)}(t - T/2, T), \quad P(\omega) = \Xi(-i\omega)^j \exp(i\omega T/2) P_g(\omega, T), \quad (10)$$

where the superscript (j) indicates j -th order differentiation, Ξ is an amplitude coefficient, and

$$p_g(t, T) = \exp\left[-\left(\frac{t}{\sigma T}\right)^2\right], \quad P_g(\omega, T) = \sqrt{\pi}\sigma T \exp\left(-\frac{\sigma^2 T^2 \omega^2}{4}\right). \quad (11)$$

Following a procedure analogous to that presented in [2] (see [4] for details), one obtains a PB expansion formally similar to (6),

$$\mathbf{e}(\mathbf{r}, t) \sim \sum_{m,p} (\mathbf{c}_{mp} \times \mathbf{u}_z) \times \mathbf{b}_{mp}(\mathbf{r}, t), \quad \mathbf{c}_{mp} = \mathbf{C}_{mp} = (L/\sqrt{2})\mathbf{g}(mL, pL). \quad (12)$$

The PB propagator \mathbf{b}_{mp} is given in the beam-centered coordinates \mathbf{r}_{bmp} by [4]

$$\mathbf{b}_{mp}(\mathbf{r}, t) = \frac{\Xi \Lambda_{mp} \sigma T}{\mathcal{T}_{mp}} p_g^{(j+1)}[(t - T/2 - \tau_{mp})\sigma, \mathcal{T}_{mp}] (\mathbf{r} - \mathbf{r}'_{mp}), \quad (13)$$

$$\begin{bmatrix} x_{bmp} \\ y_{bmp} \\ z_{bmp} \end{bmatrix} = \begin{bmatrix} \cos \theta_A \cos \phi_A & \cos \theta_A \sin \phi_A & -\sin \theta_A \\ -\sin \phi_A & \cos \phi_A & 0 \\ \sin \theta_A \cos \phi_A & \sin \theta_A \sin \phi_A & \cos \theta_A \end{bmatrix} \begin{bmatrix} x - mL \\ y - pL \\ z \end{bmatrix}, \quad (14)$$

$$\Lambda_{mp} = -\frac{L}{\sqrt{2}\pi c R_{mp}^2}, \quad \tau_{mp} = c^{-1} \left(z_{bmp} + \frac{\rho_{bmp}^2}{2z_{bmp}} + \mathcal{L}_{mp} \right), \quad (15)$$

$$T_{mp} = \frac{\rho_{bmp} L \cos \theta_A}{\sqrt{\pi} c z_{bmp}}, \quad \mathcal{T}_{mp} = \sqrt{T_{mp}^2 + \sigma^2 T^2}, \quad \rho_{bmp} = (x_{bmp}^2 + y_{bmp}^2)^{1/2}, \quad (16)$$

with $\mathbf{r}'_{mp} = mL\mathbf{u}_x + pL\mathbf{u}_y$, $R_{mp} = |\mathbf{r} - \mathbf{r}'_{mp}|$. The PB expansion in (12) involves rapidly computable analytic functions, and therefore can be evaluated very efficiently.

IV. RESULTS AND CONCLUSIONS

The PB synthesis in (12) has been validated and calibrated against a reference solution generated by Gaussian quadrature numerical integration of (2). Convergence issues have been addressed analytically in [4] and formalized in terms of nondimensional estimators. Typical results from a broad range of numerical experiments are shown in Fig. 2, for an x -polarized, square, cosine-tapered aperture field distribution

$$\mathbf{g}(x, y) = \begin{cases} \cos(\pi x/d) \cos(\pi y/d) \mathbf{u}_x, & |x|, |y| \leq d/2, \\ 0, & |x|, |y| > d/2, \end{cases} \quad (17)$$

and a fourth-order Rayleigh pulse ($j = 4$, $\Xi = T^4/30000$, $\sigma = 1/\sqrt{50}$). Figure 2 compares the reference solution and the PB synthesis (20×20 beams) for the x -component of radiated field at a fixed observation point in the near zone of the aperture. Excellent agreement is observed with the indicated number of beams, whose use is far more efficient than the Kirchhoff numerical integration. Similar results are obtained for the z -component, and also for more complicated phasing (as in rectangular focused aperture distributions) [4]. This renders the proposed pulsed beam synthesis attractive as a numerically efficient, accurate, robust algorithm for future scattering scenarios.

I. INTRODUCTION AND PROBLEM FORMULATION

This paper treats the interaction of short-pulse electromagnetic radiation with one-dimensional (1D) moderately rough dielectric interfaces, which arise in many realistic problems, such as buried object imaging. Our ultimate goal is to incorporate physics-based, computationally efficient, forward models in such inverse scattering scenarios, in order to improve the overall computational performance. In this connection, we recently analyzed time-harmonic forward and inverse scattering from moderately rough surfaces, using a Gabor-based Gaussian beam algorithm [1], [2]. Here, we extend this forward scattering algorithm to pulsed excitation, via a Physical-Optics(PO)-based approach in conjunction with the pulsed beam discretization in [3]. The problem geometry is shown in Fig. 1: a TM-polarized incident field generated by a pulsed aperture field distribution of width d at $z = z_A$ is assumed to impinge from free-space onto a lossless, nondispersive, homogeneous dielectric half-space of relative permittivity ϵ_r , bounded by a moderately rough interface described by the continuous function $h(x)$. We assume a tapered, separable, nonphased space-time field distribution

$$\mathbf{e}_y^{inc}(x, z = z_A, t) = \begin{cases} f(x)p(t - c^{-1}z_A), & |x| \leq d/2, \\ 0, & |x| > d/2, \end{cases} \quad (1)$$

where $p(t)$ is a pulse of length $T \ll d/c$, with c representing the speed of light, and $f(x)$ is the amplitude taper profile. The interface is assumed to be located in the collimation zone of the aperture so that the incident field can be approximated by

a pulsed truncated tapered plane wave propagating in the negative z -direction (see Fig. 1). Due to space limitations, we present only the main results for the scattered field, omitting technical details which can be found in [4].

II. FREQUENCY DOMAIN FORMULATION

In the proposed approach, the time domain (TD) is accessed by Fourier inversion from the frequency domain (FD) via the analytic transform (with $\omega \geq 0$). In the asymptotic high-frequency range, and for smooth roughness over all wavelength scales in the pulse spectrum, the scattered field can be approximated by integration of the PO “current” over the interface profile

$$E_y^s(x, z, \omega) \sim \int_{C_{PO}} P(\omega) J_{PO}(x') \mathbf{u}_n \cdot \nabla G_{2D}(x, z; x', h(x')) dl', \quad (2)$$

where C_{PO} extends over the illuminated portion of the surface, $P(\omega)$ is the pulse spectrum, \mathbf{u}_n is the outward normal unit vector, and dl' is the incremental arc-length. Furthermore, G_{2D} is the FD line-source Green’s function,

$$G_{2D}(x, z; x', z') = \frac{i}{4} H_0^{(1)}(\omega R/c), \quad R = [(x - x')^2 + (z - z')^2]^{1/2}, \quad (3)$$

and J_{PO} is the PO surface current density

$$J_{PO}(x) = 2\mathcal{R}(x) E_y^{inc}(x, h(x)), \quad (4)$$

with \mathcal{R} denoting the TM plane-wave Fresnel reflection coefficient, and E_y^{inc} representing the incident field.

III. TIME DOMAIN BEAM DISCRETIZATION

The PO radiation integral in (2) is not very different from the Kirchhoff aperture integrals analyzed in [3], except that the line integration in (2) is performed along a rough surface profile instead of on a projected equivalent planar aperture. In [3], the 1D space-time aperture field distribution is first parameterized in the FD in terms of x -domain discretized m -indexed Gabor basis functions with narrow width L , centered on the Gabor lattice points $x_m = mL$; these initial conditions generate *narrow-waisted*, quasi-ray, complex-source-point Gaussian beams. For Rayleigh pulses, the resulting TD analytic Fourier inversion integral can be approximated by rapidly computable closed form expressions. The same approach can be applied to discretizing PO integrals as in (2). Thus, for fourth-order Rayleigh pulses

$$p(t) = \Xi \frac{d^4}{dt^4} \exp \left[- \left(\frac{t - T/2}{\sigma T} \right)^2 \right], \quad (5)$$

one obtains the following pulsed beam (PB) expansion for the scattered field (see [3] for details)

$$e_y^s(x, z, t) \sim \sum_{|m| \leq (D/2L)} c_m b_m(x, z, t - t_m), \quad (6)$$

where the interval $[-D/2, D/2]$ spans the x -domain projection of the illuminated portion of the surface. The Gabor expansion coefficients c_m and the time delay

t_m are approximated by sampling the TD-PO surface current at the lattice points $x_m = mL$,

$$c_m = \left(\frac{L}{\sqrt{2}}\right)^{1/2} \mathcal{R}(\theta_{im}) f(x_m), \quad t_m = c^{-1}(z_A - z_m - x_m \sin \theta_{im}), \quad (7)$$

where $z_m = h(x_m)$. Moreover, $\theta_{im} = -\sin^{-1}[h'(z_m)/\sqrt{1+(h'(z_m))^2}]$ is the local incidence angle, with $h' \equiv dh/dx$, and

$$\mathcal{R}(\theta_{im}) = \frac{\cos \theta_{im} - (\epsilon_r - \sin^2 \theta_{im})^{1/2}}{\cos \theta_{im} + (\epsilon_r - \sin^2 \theta_{im})^{1/2}} \quad (8)$$

is the local TM plane-wave Fresnel reflection coefficient. The PB propagator in (6) is given by

$$b_m(x, z, t) = \text{Re} \left\{ \gamma_m \left[\mathcal{T}_m \Gamma\left(\frac{11}{4}\right) M_1\left(\frac{t - \tau_m}{\mathcal{T}_m}\right) - 2i(t - \tau_m) \Gamma\left(\frac{13}{4}\right) M_2\left(\frac{t - \tau_m}{\mathcal{T}_m}\right) \right] \right\}, \quad (9)$$

where

$$\gamma_m = -i \frac{16 \cdot 2^{1/4} \exp(i\pi/4) L^{1/2} \sigma \Xi T [\sin \theta_{im}(x - x_m) - \cos \theta_{im}(z - z_m)]}{\pi c R_m^{3/2} \mathcal{T}_m^{13/2}},$$

$$\tau_m = \frac{x_m \sin \theta_{im} + R_m + T/2}{c}, \quad T_m = \frac{L \cos^2 \theta_{im}}{c(8\pi)^{1/2}} \left(1 - \frac{z_{bm}}{R_m}\right)^{1/2}, \quad \mathcal{T}_m = (T_m^2 + \sigma^2 T^2)^{1/2},$$

and (x_{bm}, z_{bm}) are beam-centered coordinates,

$$\begin{bmatrix} x_{bm} \\ z_{bm} \end{bmatrix} = \begin{bmatrix} \cos(2\theta_{im}) & -\sin(2\theta_{im}) \\ \sin(2\theta_{im}) & \cos(2\theta_{im}) \end{bmatrix} \begin{bmatrix} x - x_m \\ z - z_m \end{bmatrix}, \quad R_m = (x_{bm}^2 + z_{bm}^2)^{1/2}.$$

Moreover, in (9), $\Gamma(\cdot)$ denotes the gamma function [5], and

$$M_1(t) = {}_1F_1\left(\frac{11}{4}, \frac{1}{2}, -t^2\right), \quad M_2(t) = {}_1F_1\left(\frac{13}{4}, \frac{3}{2}, -t^2\right), \quad (10)$$

where ${}_1F_1(u, v, t)$ is the Kummer confluent hypergeometric function [5]. The functions M_1 and M_2 can be efficiently computed using a rapidly converging power series expansions derived in [3]. The propagator in (9) is a pulsed Gaussian beam, whose collimation is controlled by the discretization period L . The expansion in (6) yields accurate syntheses for $L \ll D$, i.e., for *narrow-waisted*, poorly collimated PB propagators.

The corresponding expansion for the transmitted field can be obtained similarly, as can results for oblique incidence and slight Ohmic losses [4].

IV. RESULTS AND CONCLUSIONS

In order to validate and calibrate the above algorithm, we developed an independent reference solution, based on the time-harmonic multifilament current method exploited in [1]. The spectrum of the scattered field was obtained by solving the scattering problem at 100 different frequencies within the pulse bandwidth. The

resulting frequency samples were smoothed through local Padé-approximation and filtered by the pulse spectrum $P(\omega)$. The TD solution was then obtained by standard inverse FFT algorithms. Typical results are shown in Fig. 2. Specifically, for the temporal behavior of the scattered field at a fixed observation point in the presence of the the interface profile in Fig. 2a, Fig. 2b shows the comparison between the reference solution and the PB synthesis (100 beams) in (6), which involves a modest computational effort when compared with conventional Kirchhoff-PO integration. Good agreement is observed even in the finer details. Convergence and accuracy issues are discussed in [4]. Similar results have been obtained for the transmitted field. Applications to inverse-scattering scenarios are presently under consideration.

I. PROBLEM FORMULATION

The problem of determining the properties of rough surfaces from electromagnetic scattered field data arises in many important subsurface sensing problems such as underground imaging using data from a Ground Penetrating Radar (GPR). In GPR systems, arrays of above-ground transmitters and receivers illuminate areas of interest and receive backscattered signals from shallowly buried objects and from surface reflections. The shape of the air-ground interface is unknown, and it is a principal corruptor of the backscattered signal from subsurface targets of interest. In order to enhance subsequent detection, classification and inverse scattering processing, it is important to compensate for the distortion introduced by the air-ground interface. As a first step toward this goal, in a recent investigation [1] we addressed the problem of estimating the profile of one-dimensional (1D) moderately rough dielectric interfaces from a limited number of multifrequency measurements under time-harmonic excitation. In this paper, we extend the approach to the case of time-dependent (short pulse) excitation. The proposed extension is based on a recently developed Gabor-based narrow-waisted pulsed-beam (PB) representation of short-pulse scattering by moderately rough surfaces [2].

The problem geometry is depicted in Fig. 1: in an (x, z) 2D coordinate space, a TM-polarized incident field generated by a pulsed aperture field distribution of width

*Work supported by ODDR&E under MURI grants ARO DAAG55-97-1-0013 and AFOSR F49620-96-1-0028, and by the Engineering Research Centers Program of the National Science Foundation under award number EEC-9986821. d at $z = z_A$ is assumed to impinge from free-space onto a lossless, nondispersive, homogeneous dielectric half-space of known relative permittivity ϵ_r , bounded by a moderately rough interface described by the continuous function $h(x)$. We assume a tapered, separable, nonphased space-time aperture field distribution

$$e_y^{inc}(x, z = z_A, t) = \begin{cases} f(x)p(t), & |x| \leq d/2, \\ 0, & |x| > d/2, \end{cases} \quad (1)$$

where $p(t)$ is a pulse of length $T \ll d/c$, with c representing the speed of light, and $f(x)$ is the amplitude taper profile. The interface is located in the collimation zone of the aperture so that the incident field can be approximated by a pulsed truncated tapered plane wave propagating in the negative z -direction (see Fig. 1). The y -directed scattered field e_y^s is sampled at N_t time instants at N_r receiver locations (at $z = z_{obs}$). This setup is typical of GPR systems for detecting shallowly buried anti-personnel mines, of interest for humanitarian demining. However, in this investigation we ignore the presence of any buried objects. Furthermore, we are not taking into account the *noisy* (incoherent) contribution of finer-scale roughness, and we aim to estimate the coarse shape of the surface, acknowledging the implicit limits of retrievable information through inverse scattering. Due to the inherent *ill-posedness* of this kind of inverse scattering problems, it is essential to incorporate stabilization steps, known as regularization methods. As in [1], we introduced an “implicit” regularization by exploiting an appropriate discrete representation of the surface. Accordingly, the surface estimation problem is posed as a nonlinear optimization problem, whose solution requires repeated evaluations of the scattered field at the receiver locations. The efficiency of such an approach thus strongly relies on the availability of a fast forward scattering model.

II. FORWARD MODEL

Our forward scattering model is detailed in [2]. Technically, it is based on the Kirchhoff Physical Optics (PO) approximation and on the Gabor-based narrow-waisted PB discretization of 1D aperture field distributions in [3]. The time domain is accessed by analytic Fourier inversion, starting from the frequency domain PO model discretized in terms of *complex source point* narrow-waisted *quasi-ray* Gaussian beams. For the class of Rayleigh (differentiated Gaussian) time pulses we obtained closed form solutions in terms of rapidly computable analytic functions [2]. The algorithm has been validated and calibrated against an independently generated reference solution based on an extension [2] of the multifilament current method [4]. This reference solution is also used to simulate the measured data needed in the inversion procedure (see Sec. III). The proposed forward scattering model has been shown capable of furnishing accurate and numerically efficient predictions in a calibrated range of parameters, so that it appears to be suitable for the inverse scattering scenario described in Sec. I.

III. TIME DOMAIN INVERSION APPROACH

As stated previously, the proposed *robust* inversion strategy is based on a low-dimensional compact geometrical parameterization of the unknown interface profile, whose unknown parameters are estimated by *fitting* the model-based forward

scattering prediction to the available (measured/simulated) data, i.e., minimizing a suitable *error functional*. The choice of the interface profile parameterization requires tradeoff between compactness and versatility, keeping in mind that the number of unknown parameters N to be estimated must be *smaller* than the collected scattered field data size, i.e., $N \sim N_r \times N_t$. We assume that the surface shape can be approximated by a finite set of quartic B-spline basis functions with unknown coefficients,

$$h(x) \approx \sum_{n=1}^N c_n s_4(x). \quad (2)$$

Let $E_{pq}^s = E_y^s(x_p, t_q)$ denote the y -directed scattered field *measured* at time t_q at sensor position x_p . Given a vector of spline coefficients $\underline{c} = \{c_1, \dots, c_N\}$ and the outgoing field from the aperture distribution in (1), we can use the PB algorithm in [2] for the surface profile in (2) to generate predictions of the scattered field waveforms at each receiver. Let $e_{pq}^s = e_y^s(x_p, t_q; \underline{c})$ denote the *model-based prediction* of the scattered field at time t_q at sensor position x_p , for surface profile coefficients \underline{c} . With this notation, we define the error functional as follows

$$J(\underline{c}) = \|\underline{\mathbf{e}}^s(\underline{c}) - \underline{\mathbf{E}}^s\|^2, \quad (3)$$

where $\underline{\mathbf{e}}^s = \{e_{pq}^s\}$, $\underline{\mathbf{E}}^s = \{E_{pq}^s\}$, $p = 1, \dots, N_r$, $q = 1, \dots, N_t$. As anticipated, the measured data are simulated via the reference solution described in [2]. The regularized inverse scattering problem can now be formalized as finding the coefficient vector \underline{c} in (2) which minimizes the error functional $J(\underline{c})$ in (3), i.e. finding $\hat{\underline{c}}$ such that

$$\hat{\underline{c}} = \arg \min_{\underline{c}} J(\underline{c}). \quad (4)$$

This minimization is nontrivial since the cost functional in (4) is likely non-convex with respect to \underline{c} . Therefore, standard descent-based optimization algorithms are prone to get stuck in local minima, and global optimization techniques are needed. In the frequency domain approach, i.e., for frequency-stepped time-harmonic excitation [1], we used a *continuation method* based on the selected use of the data at the various available frequencies. We are presently working on the extension of this *multiresolution* optimization strategy to the case of short-pulse excitation.

IV. RESULTS AND CONCLUSIONS

To illustrate the results achievable with our technique we show in Fig. 2 a reconstruction example for stepped frequency GPR measurements, obtained using the algorithm in [1]. The soil was modeled as lossless, nondispersive, with relative permittivity $\epsilon_r = 3$. The maximum slope of the rough surface profile is 34° . The interrogating field is generated by a cosine-tapered aperture field distribution of width $d = 0.8$ located at $z_A = 0.6$. The complex scattered field is measured at 10 equispaced observation points at $z_{obs} = 0.6$ spanning the illuminated region, and at four operating wavelengths ($\lambda = 0.2, 0.1, 0.067, 0.05$). The length scales are normalized with respect to the smallest radius of curvature R_c of the local interface profile maxima; it has been shown in [5] that for $\lambda/R_c \lesssim 0.2$, the high-frequency narrow-waisted beam algorithm actually works well over the range of problem parameters in our example here, although the lower limit $\lambda/R_c \sim 0.2$ is in

the “low frequency” region. The resulting error functional to be minimized is similar to (3), and the multiresolution minimization strategy detailed in [1] is exploited. As one can see, the reconstruction is accurate throughout most of the interval, except near the edges of the illumination region. This kind of accuracy was observed in many numerical experiments, even in noisy environments [1].

We are currently conducting numerical experiments with short pulse GPR excitations. These results will be reported at the conference.

Abstract— An adaptive framework is presented for wide-band ground penetrating radar imaging of low-contrast buried objects in the presence of a moderately rough air-soil interface. The proposed approach relies on recently developed Gabor-based narrow-waisted Gaussian beam algorithms as fast forward scattering predictive models. A prior nonlinear inverse scattering problem is solved to estimate the unknown coarse scale roughness profile. The Born-linearized underground imaging problem is subsequently solved compensating for the clutter effect produced by the estimated roughness profile. Preliminary outcomes indicate that the proposed framework is attractive as compared to standard statistical approaches.

I. INTRODUCTION

In ground penetrating radar (GPR) applications, modelling the distortion, introduced by a twice-traversed rough air-ground interface, in the interrogating signal on its way to and from the targets of interest is a key issue. Standard statistical approaches, which tend to model such distortion as an additive colored Gaussian noise, perform reasonably well in *detection* problems [1], but have been found to yield limited accuracy and robustness in *classification* and *reconstruction* (see, e.g., [2]).

In this paper, with particular reference to the problem of anti-personnel plastic land mine detection/classification via wide-band GPR, we present a novel *adaptive* approach, based on a prior estimation of the unknown coarse scale roughness profile and a subsequent *quasi-deterministic* compensation of the related clutter. The proposed approach is built on recently developed Gabor-based narrow-waisted Gaussian beam (GB) algorithms for short-pulse scattering from, and transmission through, moderately rough dielectric interfaces [3]. By exploiting these fast for-

Fig. 1. Problem geometry.

ward models, the prior surface estimation is posed as a nonlinear optimization problem [4]. A beam-computed Green's function accounting for the distortion introduced by the estimated roughness profile is exploited in the subsequent underground imaging problem, which is linearized via Born approximation [5] and solved for the unknown dielectric permittivity contrast, using various *point-wise* and *object-based* reconstruction techniques.

II. ROUGH SURFACE FORWARD SCATTERING

The problem geometry is sketched in Fig. 1: in an (x, z) two-dimensional (2D) coordinate space, a lossy homogeneous dielectric half-space (soil) of known relative permittivity ϵ_r and conductivity σ , bounded by a moderately rough interface $z = h(x)$, is illuminated by a y -directed (TM-polarized) pulsed field generated by a truncated aperture field distribution of width d at $z = z_A$. We assume that the incident field can be approximated by a pulsed truncated tapered plane wave propagating in the negative z -direction (Fig. 1),

$$e^i(\mathbf{r}, t) \sim g(x)p[t - c^{-1}(z - z_A)], \quad (1)$$

where $\mathbf{r} \equiv (x, z)$, $p(t)$ is a pulse of length $T \ll d/c$, with c representing the speed of light, and $g(x)$ is the taper profile. In this preliminary investigation, we ignore the presence of buried targets.

The forward scattering model, detailed in [3], is based on the Kirchhoff Physical Optics (PO) approximation in conjunction with the Gabor-based narrow-waisted pulsed beam (PB) discretization of 1D aperture field distributions in [6], and is restricted to moderate roughness (both in height and slope) and slightly lossy soils. The PO equivalent currents, which generate reflected and transmitted fields, are first parameterized in the frequency domain in terms of x -domain discretized m -indexed Gabor basis functions with narrow width L , centered on the Gabor lattice points $x_m = mL$; these initial conditions generate *narrow-waisted*, quasi-ray, complex-source-point GBs propagating along the local reflection/refraction directions. For Rayleigh (i.e., differentiated Gaussian) pulses, the resulting time domain analytic Fourier inversion integral can be approximated by rapidly computable closed form expressions. One obtains the following approximate PO-PB expansions for reflected and transmitted fields e^r and e^t , respectively (see [3] for details),

$$e^\nu(\mathbf{r}, t) \sim \sum_{|m| \leq (d/2L)} a_m^\nu b_m^\nu(\mathbf{r}, t - t_m), \quad \nu = r \text{ or } t, \quad (2)$$

where the Gabor expansion coefficients a_m^ν and the time delays t_m are approximated by sampling the PO equivalent currents at the lattice points $x_m = mL$, and the PB propagators b_m^r and b_m^t are expressed in terms of rapidly computable confluent hypergeometric functions [3].

III. INVERSE SCATTERING

A. Rough interface estimation

The interface estimation problem has been addressed in [7] for frequency-stepped time-harmonic excitation and *sparse* data, and has been extended in [4] to pulsed excitation. Here, we briefly review the pulsed case. Due to the inherent *ill-posedness* of the problem, we exploit a *robust* inversion strategy based on an appropriate compact low-dimensional representation of the roughness profile, whose unknown parameters are estimated by fitting the PO-PB forward scattering prediction to the available (measured/simulated) data, i.e., minimizing a suitable *cost functional*. The resulting *nonlinear* optimization problem requires repeated evaluations of the reflected field at the receiver locations, and therefore its computational efficiency is strongly tied to the efficiency of the PO-PB algorithm. We found that a quartic spline parameterization

$$h(x) \approx \sum_{n=1}^N c_n s_n^{(4)}(x), \quad (3)$$

provides a good tradeoff between versatility and computational burden. In (3), c_n are unknown coefficients, and $s_n^{(4)}$ represents a quartic B-spline basis function. With $\hat{e}_{pq}^r = \hat{e}^r(x_p^r, z^r, t_q)$ denoting the y -directed reflected field *measured* at time t_q at receiver

location (x_p^r, z^r) (Fig. 1), and $e_{pq}^r = e^r(x_p^r, z^r, t_q; \underline{c})$ denoting the corresponding PO-PB *forward prediction* for surface profile coefficients $\underline{c} = \{c_1, \dots, c_N\}$, we formalize the *regularized* inverse scattering problem as finding the coefficient vector \underline{c} in (3) which minimizes the cost functional

$$J(\underline{c}) = \|\underline{e}^r(\underline{c}) - \hat{\underline{e}}^r\|^2 = \sum_{p=1}^{N_r} \sum_{q=1}^{N_t} \gamma_p (e_{pq}^r - \hat{e}_{pq}^r)^2, \quad (4)$$

where N_r is the number of receivers, N_t the number of time samples at each receiver, and γ_p are normalization coefficients. The cost functional in (4) is generally *non-convex* with respect to \underline{c} , and therefore the possible presence of local minima renders its minimization non-trivial. The resulting global optimization strategies and computational issues are discussed in [4].

B. Underground imaging

We again refer to the problem geometry in Fig. 1, but now include a buried plastic target with dielectric permittivity $\epsilon_r^{(tar)}$ and conductivity $\sigma^{(tar)} \approx 0$ occupying the region $D^{(tar)}$ in the half-space $z < h(x)$. The TM-polarized *total* field observed at the receiver location $\mathbf{r}^r = (x^r, z^r)$ can be written as

$$e(\mathbf{r}^r, t) = e^b(\mathbf{r}^r, t) + e^s(\mathbf{r}^r, t), \quad (5)$$

where e^b represents the *background field* (the field in the absence of the target, i.e., e^r in (2)), and

$$e^s(\mathbf{r}^r, t) = - \iint_{D^{(tar)}} \left\{ \frac{\Delta\epsilon_r(\mathbf{r}')}{c^2} \partial_t^2 [g_b(\mathbf{r}^r, \mathbf{r}', t, t') \otimes e(\mathbf{r}', t')] + \frac{\sigma}{c\epsilon_0} \partial_t [g_b(\mathbf{r}^r, \mathbf{r}', t, t') \otimes e(\mathbf{r}', t')] \right\} d\mathbf{r}' \quad (6)$$

is the field scattered by the target. In (6), the *object function* $\Delta\epsilon_r \equiv (\epsilon_r^{(tar)} - \epsilon_r)$ represents the unknown relative permittivity contrast, c is the speed of light, g_b denotes the space-time Green's function of the rough-interface dielectric half-space, e is the *total* field in the target region for pulsed excitation $p(t)$, and \otimes indicates time convolution. Assuming that an estimation of the rough interface profile is available, one can generate prediction of the background field contribution e^b in (5) for a given pulsed excitation, and hence *isolate* the contribution e^s from the target. For plastic anti-personnel land mines, of particular interest in our investigation, the dielectric properties of the target are typically close to those of the background soil, i.e., $\epsilon_r^{(tar)} \approx \epsilon_r$. Accordingly, one can exploit the *weak-scattering* Born approximation [5],

$$e(\mathbf{r}', t') \approx e^t(\mathbf{r}', t'), \quad \mathbf{r}' \in D^{(tar)}, \quad (7)$$

where the *total* field e inside the target is approximated by the *transmitted* field e^t in the target region *in the absence of the target*, thus yielding in (6) a *linear* model relating the scattered field at the receivers to the dielectric contrast $\Delta\epsilon_r$. The needed convolutions $g_b \otimes e^t$ and their time derivatives in (6) with (7)

can be efficiently computed using PO-PB expansions similar to (2).

Based on the linear forward scattering model in (6) and (7), and on a number of observations of the scattered field waveforms at the receivers, an inversion scheme can be constructed by discretizing the test domain $D^{(test)}$ to be imaged into a number of adequately small pixels. Assuming that N_t time samples of the scattered field e^s are collected at N_r receivers, and that the test domain is discretized into N_p pixels, the linear forward model in (6) and (7) can be discretized accordingly and cast into matrix form as

$$\underline{y} = \underline{A} \cdot \underline{x} + \underline{n}, \quad (8)$$

where \underline{y} is a column vector containing the $N_r \cdot N_t$ time samples of the *known term* in (6) and (7),

$$e^s(\mathbf{r}^r, t) + \frac{\sigma}{c\epsilon_0} \iint_{D^{(test)}} \partial_t [g_b(\mathbf{r}^r, \mathbf{r}', t, t') \otimes e^t(\mathbf{r}', t')] d\mathbf{r}', \quad (9)$$

\underline{x} is a N_p -element column vector containing the *unknown* dielectric contrast $\Delta\epsilon_r$ at each pixel, \underline{A} is a $(N_r \cdot N_t) \times N_p$ matrix containing the space-time discretization of the integral

$$-c^{-2} \iint_{D^{(test)}} \partial_t^2 [g_b(\mathbf{r}^r, \mathbf{r}', t, t') \otimes e^t(\mathbf{r}', t')] d\mathbf{r}', \quad (10)$$

and the *noise* vector \underline{n} accounts for measurement uncertainty and unmodeled effects. Due to the inherent ill-posedness of this inverse scattering problem, and the various approximations in our model, it is essential to introduce some regularization. In this connection, we have explored various *edge-preserving* regularization approaches such as *total variation* [2] and *curve evolution* [8]. In total variation regularization, the problem is posed as the minimization of the functional

$$\Phi(\underline{x}) = \|\underline{y} - \underline{A} \cdot \underline{x}\|^2 + \lambda_1 \|\underline{K} \cdot \underline{x}\|^2 + \lambda_2 \|\underline{D} \cdot \underline{x}\|^1, \quad (11)$$

where the parameters λ_1 and λ_2 are usually determined empirically, \underline{D} is a spatial gradient operator, and the operator \underline{K} penalizes negative values of the reconstructed object function (the sign of the object function $\Delta\epsilon_r$ is assumed to be known a priori)

$$[\underline{K} \cdot \underline{x}]_i = \begin{cases} x_i, & x_i < 0, \\ 0, & x_i \geq 0. \end{cases} \quad (12)$$

In (11), the L_1 norm on the spatial gradient term encourages piecewise smoothness in the reconstructed object function and, unlike the L_2 norm in standard Tikhonov regularization, allows sharp edges to form, yielding visually better (less blurred) reconstructions. Alternatively, one can exploit *object-based* reconstruction approaches, applicable to piece-wise smooth object functions, where instead of a *point-wise* reconstruction one focuses on the *direct estimation* of the target boundary and the dielectric contrast value, with a considerable saving in the number of unknowns and a consequent better conditioning of the problem.

Fig. 2. Simulation geometry and parameters. Soil: $\epsilon_r = 3$, $\sigma = 0.01$ S/m. Target: $10\text{cm} \times 6\text{cm}$ ellipse with center at 10cm below nominal ground, $\epsilon_r^{(tar)} = 3.3$. Excitation: cosine-tapered aperture field distribution ($z_A = 30\text{cm}$, $d = 80\text{cm}$), fourth-order Rayleigh wide-band excitation (2.45 GHz center frequency, 1.4 GHz bandwidth). Test domain: $20\text{cm} \times 20\text{cm}$ square (30×30 pixels, i.e., $N_p = 900$). $N_r = 11$ equispaced receivers at 20cm above nominal ground.

This is usually accomplished via curve evolution techniques, i.e., by designing a gradient flow which attracts initial closed curves to the target boundary (see [8] for details).

IV. RESULTS

The simulation geometry and parameters are illustrated in Fig. 2. We consider a plastic mine-like $10\text{cm} \times 6\text{cm}$ elliptic target with relative permittivity $\epsilon_r^{(tar)} = 3.3$ shallowly buried in a homogeneous dielectric half-space with constitutive parameters chosen so as to simulate a class of realistic sandy soils ($\epsilon_r = 3$, $\sigma = 0.01\text{S/m}$). The rough surface realization, parameterized in this experiment with 20 B-spline basis functions, was generated randomly so as to mimic typical ($\sim 3 - 4$ cm peak-to-peak, maximum slope $\sim 30^\circ$) natural (moderate) roughness. A cosine-tapered transverse field distribution of aperture width $d = 80\text{cm}$ was chosen, with a fourth-order Rayleigh wide-band excitation (2.45 GHz center frequency, 1.4 GHz bandwidth). Synthetic field measurement data were generated via full-wave solution of the forward scattering problem (see [3] for details). A $20\text{cm} \times 20\text{cm}$ square test domain surrounding the target to be imaged was discretized in 30×30 pixels. In this experiment, $N_r = 11$ equispaced receivers at 20cm above nominal ground were used.

For the interface estimation problem, $N_t = 100$ time samples of the *early-time* response (i.e., excluding causal contributions from the test domain) at each receiver were used in the cost functional (4), thus avoiding any possible bias due to target scattering. The cost functional (4) was minimized using the conjugate gradient (CG) strategy described in [4], assuming as initial guess a flat interface at $z = 0$. A typical reconstruction example is shown in Fig. 3. The reconstruction is quite accurate throughout most of the interval, except near the edges of the illumina-

Fig. 3. Parameters as in Fig. 2. Rough interface profile reconstruction example ($N_t = 100$).

Fig. 4. Parameters as in Fig. 2. Underground imaging examples ($N_t = 300$). (a): Ground truth ($\Delta\epsilon_r = 0.3$). (b): Total variation reconstruction with adaptive compensation. (c): Curve evolution reconstruction with adaptive compensation; estimated target boundary (white curve) is superposed on ground truth; estimated dielectric contrast: $\Delta\epsilon_r = 0.32$. (d): Total variation reconstruction without compensation (flat interface at $z = 0$).

tion region. This kind of accuracy was observed in many numerical experiments, with CG convergence typically achieved in 30 – 40 iterations.

The obtained interface estimation was used to compute the background field e^b in (5), and hence isolate the target contribution e^s . For the underground imaging problem, $N_t = 300$ time samples of the *late-time* response (i.e., causally related to the test domain) were used. The data matrix $\underline{\underline{A}}$ and the known term \underline{y} in (8) were computed using a PO-PB algorithm similar to (2). Both total variation (via the iterative scheme in [2]) and curve evolution (using the algorithm in [8]) reconstructions were attempted. The underground imaging algorithms are still under investigation, and are not yet fully optimized and calibrated. Some preliminary results are shown in Fig. 4. Specifically, the true object function (ground truth) is shown in Fig. 4a, and the corresponding total variation and curve evolution reconstructions are shown in Figs. 4b and 4c, respectively. It is observed that total variation, though not yielding a highly accurate

point-wise reconstruction, provides a reasonably accurate target localization. On the other hand, curve evolution provides rather accurate direct estimations of *both* target boundary *and* dielectric contrast. Note that the limited viewing geometry renders the problem *more ill-posed* in the horizontal direction, resulting in less accurate horizontal localization in both cases. The effect of the interface roughness and the importance of adaptive compensation is highlighted in Fig. 4d, where a total variation reconstruction *without* any compensation (i.e., assuming a flat interface at $z = 0$) is shown. The poor quality of the reconstruction can be only slightly improved using statistical processing, as shown in [2], but is still not comparable to that of Figs. 4b,c.

V. CONCLUSIONS

An adaptive approach for rough surface underground imaging has been presented, which exploits short-pulse Gabor-based narrow-waisted Gaussian beam algorithms as fast forward scattering models. Preliminary 2D results, restricted to slightly lossy soils with moderate roughness and low-contrast targets, show that quite accurate estimations of the coarse scale roughness profile can be obtained from reflected field sparse data, and can be fruitfully exploited to enhance underground imaging, with reasonable computing time and resources.

Abstract

This paper develops new approaches for imaging weak-contrast buried objects using data from a ground penetrating radar array. An approximate physical model relating the collected data to the underground objects is developed. This model uses ray optics to represent the air/soil interface, and a Born approximation to model the weak contrast back-scattering from buried objects. In order to address both modeling errors and ill-posedness, the proposed image reconstruction algorithms use regularization based on a total variation norm with orientation preference. The algorithms are tested on data generated by nonlinear finite difference time domain electromagnetic simulations.

1 Introduction

Problems of locating and reconstructing physically inaccessible objects arise in many different applications such as landmine detection and removal, seismic imaging, archaeological surveying, and hydrology. Many of these applications require techniques for accurate imaging that provide reliable information about buried objects' physical properties. This is particularly difficult when there is weak contrast between the properties of the buried object and the surrounding soil.

This paper focuses on underground imaging techniques for weak contrast buried objects using electromagnetic Ground Penetrating Radar(GPR). GPR is the preferred approach for detection and localization of plastic mines [4], where the traditional metal detectors fail. The approach proposed in this paper is based on the principles of diffraction tomography [5][6] for imaging weak-contrast dielectric objects. In diffraction tomography, the imaging problem is posed as an inverse scattering problem, and a physically-based linear model is used to define the relationship between collected data and buried objects' properties. Reconstructing an estimate of the objects' profiles is thus a linear inversion problem, for which many techniques have been developed based on singular value decompositions, regularization and optimization methods [7].

For the problems of interest in this paper, there are two major physical effects to consider: propagation through an air-ground interface, and backscattering from objects buried underground. The air/soil interface is modeled using ray optics. For backscattering, the physical models are based on the Born approximation in inverse scattering. This is because there is low contrast between the soil and mine permittivities ($\epsilon_{soil} = 2.6$, $\epsilon_{mine} = 2.9$), resulting in weak scattering. The resulting linear models relate the received signals to the transmitted signals and the underlying underground objects. This linear transformation is approximate and ill-conditioned, requiring algorithms which are robust to modeling errors and sensor noise.

Our proposed approach for inversion is based on robust regularization. Since edge information is important for delineating buried objects, we use total variation regularization [9], instead of conventional regularization techniques such as Tikhonov and singular value decomposition methods which result in blurred edges. Furthermore, we exploit the structure of the vertical illumination geometry for buried objects to introduce different levels of horizontal and vertical regularization. The rest of this paper is organized as

follows. Section 2 introduces the configuration of the underground imaging system. Section 3 contains the model of the backscattering through a flat air/soil surface. Section 4 describes the total variation based regularization method. Section 5 compares the performance of the proposed algorithms with that of standard regularization techniques on examples generated using high-fidelity nonlinear simulations.

2 Imaging System Configuration

The underground imaging system of interest consists of an array of GPR transmitters and a different array of receivers, both located above ground. Fig. 1 shows the geometry of the sensor and object configuration. To simplify the analysis, we consider a two-dimensional problem with transverse magnetic(TM) polarization mode for the signal, a flat interface between air and soil, and uniform relative permittivity for the background soil. The combined GPR transmitters generate a short pulse TM wave, approximated by a plane wave in the region of interest, propagating perpendicular to the soil. The pulse width is approximately 0.8 nanoseconds, corresponding to a 1.25 GHz bandwidth.

Interactions between the transmitted wave and the soil result in part of the plane wave penetrating the underground soil. This wave interacts with the buried object, generating backscattered signals which must propagate through the ground/air interface and up to the receivers.

The region enclosed by the dash lines is the region of interest for reconstruction. Since the TM mode is used, the magnetic field orientation is perpendicular to the planar geometry, so only its H_z component is non-zero. Similarly, the electric field has components only in the plane, so only E_x and E_y are non-zero. Although the transmitted signal has negligible E_y component because of its plane wave orientation, the backscattered signal will have both E_x and E_y components. We assume that the receivers are polarized, and receive only the contribution of the E_x field.

Figure 1: Geometry of the sensor and mine configuration

3 Problem Formulation

The basic mechanism for backscattering is due to a difference in the relative permittivities of the objects of interest and the surrounding background soil. We assume that the object of interest is described by the “object function” at position \vec{r} as

$$O(\vec{r}) = n(\vec{r})^2 / n_{soil}^2 - 1 \quad (1)$$

where $n(\vec{r}) = \sqrt{\mu(\vec{r})\epsilon(\vec{r})}$ is the square root of the product of the relative permeability and permittivity at \vec{r} . For the imaging problems of interest, the relative permeabilities of the object and background are close: $\mu(\vec{r}) \approx \mu_{soil} \approx 1$. Thus,

$$O(\vec{r}) = n(\vec{r})^2 / n_{soil}^2 - 1 = \epsilon(\vec{r}) / \epsilon_{soil} - 1 \quad (2)$$

The field $u(\vec{r}, t)$ satisfies the wave equation

$$\left[\nabla^2 - \frac{1}{v(\vec{r})^2} \partial_t^2 \right] u(\vec{r}, t) = 0 \quad (3)$$

where $v(\vec{r})$ is the wave propagation speed at position \vec{r} , which is related to the relative permittivity by

$$v(\vec{r}) = v_{soil} \sqrt{\frac{\varepsilon_{soil}}{\varepsilon(\vec{r})}} \quad (4)$$

where v_{soil} is the wave propagation speed in soil. Under the time-dependent Born approximation, the field scattered by the buried object can be expressed in the form

$$u(\vec{r}, t) \propto -\partial_t^2 \int d\vec{r}' \int dt' O(\vec{r}) u^i(\vec{r}', t') G(\vec{r}, t; \vec{r}', t') \quad (5)$$

where $u^i(\vec{r}', t')$ is the incident pulsed plane wave, and $G(\vec{r}, t; \vec{r}', t')$ is the time-dependent Green's function in the presence of the air/soil interface determining the field strength at \vec{r}, t from a point source at \vec{r}', t' . Note that, although the buried object is assumed to be in weak contrast with the soil, the air properties are strongly in contrast with that of the soil, and thus some care is required to compute the Green's function G . Fig 2 shows the reflection and refraction of the TM mode at the air/soil interface. Given source position a and destination position c , according to Snell's law, $\frac{\sin\theta_1}{\sin\theta_2} = \sqrt{\frac{\mu_2 \varepsilon_2}{\mu_1 \varepsilon_1}} \approx \sqrt{\frac{\varepsilon_2}{\varepsilon_1}}$, so we can determine the position b on the air/soil interface. Since the received measurement consists of E'_x , the field of interest $u(\vec{r}, t) = E'_x(\vec{r}, t)$ in our problem. The refraction coefficient of E'_x is given by

$$\Gamma = \frac{E'_x}{E} = \frac{2\cos\theta_1\sin\theta_2\cos\theta_2}{\sin(\theta_1 + \theta_2)\cos(\theta_1 - \theta_2)} \quad (6)$$

Using this model, the time-dependent Green's function in the presence of an air/soil interface can be

Figure 2: Reflection and refraction in TM mode

expressed as

$$G(\vec{r}, t; \vec{r}', t') = \frac{\Gamma \delta(t - t' - \overline{ab}/v_{soil} - \overline{bc}/v_{air})}{2\pi(\sqrt{\varepsilon_{soil}}\overline{ab} + \overline{bc})} \quad (7)$$

where \overline{ab} and \overline{bc} are the distances between a, b , and b, c respectively.

Based on the Born approximation presented in (5), we build the inversion scheme by sampling the measured E_x fields at each receiver and discretizing the object function. Including observation noise, the resulting model from (5) can be put into a matrix form as

$$y = Ax + n \quad (8)$$

where $y = [y_1^T | y_2^T | \cdots | y_N^T]^T$, and y_i is a column vector containing the sampled time signal collected by the i th receiver. The area of interest is discretized into M cells and x denotes a column vector which represents the object function in the area of interest. The matrix A is the discretized integral of (5), and n represents noise due to discretization or measurement error.

4 Regularization Method

The matrix A is both ill-conditioned, and based only on an approximation of the true physics. In order to obtain accurate reconstructions, we use regularization techniques to introduce additional information in the reconstruction algorithms. Since the object function is piecewise smooth and the mine's relative permittivity is larger than that of the soil, we use two different regularization functionals to encourage smoothness and positivity of the reconstructed object function. With the conventional Tikhonov regularization, the reconstruction problem minimizes the following objective:

$$\hat{x} = \arg \min_x \|y - Ax\|_2^2 + \lambda_1 \|Kx\|_2^2 + \lambda_2 \|Dx\|_2^2 \quad (9)$$

where D is the spatial gradient operator and K is defined by

$$[Kx]_i = \begin{cases} x_i & \text{if } x_i < 0 \\ 0 & \text{otherwise} \end{cases} \quad (10)$$

which penalizes negative values of the reconstructed object function.

To accurately locate a buried object, precise edge information is desired. However, with the conventional Tikhonov regularization (8), the edges in the reconstructed mine profiles tend to be blurred. As an alternative, we propose to use total variation regularization, which has better edge-preserving properties. In total variation regularization, the original L_2 norm on the piecewise smoothness penalty term is replaced with an L_1 norm, which penalizes large jumps less than the L_2 norm and thus allows sharp edges to form in reconstructed object profiles. The total variation based regularization objective is:

$$\begin{aligned} \hat{x} = & \arg \min_x \|y - Ax\|_2^2 + \lambda_1 \|Kx\|_2^2 \\ & + \lambda_2 \sum_{i=1}^M \sqrt{\alpha [D_x x]_i^2 + (2 - \alpha) [D_y x]_i^2} \end{aligned} \quad (11)$$

where D_x and D_y denote the first derivative operators in the horizontal and vertical directions respectively, and α controls the orientation preference of the smoothness regularization term. When $\alpha = 1$, there is no orientation preference. A regularization with orientation preference is desirable because the limited viewing geometry results in higher resolution in the vertical direction than in the horizontal direction. Thus, the problem is more “ill-posed” in the horizontal direction, and needs stronger regularization in that direction.

Equation (11) can be solved iteratively based on “half-quadratic” approximations[9], as follows. Let $x^{(k)}$ denotes the solution in the k th iteration step. Let

$$G^{(k)} = \text{diag} \left[\frac{1}{\sqrt{\alpha [D_x x^{(k)}]_i^2 + (2 - \alpha) [D_y x^{(k)}]_i^2 + \beta^2}} \right] \quad (12)$$

where β is a small smoothing parameter, which controls the the closeness to the true L_1 norm solution and the convergence speed. Let $P^{(k)} = \text{diag} [p_i^{(k)}]$, where $p_i^{(k)} = \begin{cases} 1 & \text{if } x_i^{(k)} < 0 \\ 0 & \text{otherwise} \end{cases}$. Then, the next solution $x^{(k+1)}$ is obtained by solving the following linear equation:

$$\begin{aligned} \left[A^T A + \lambda_1 P^{(k)} + \frac{\lambda_2}{2} \alpha D_x^T G^{(k)} D_x \right. \\ \left. + \frac{\lambda_2}{2} (2 - \alpha) D_y^T G^{(k)} D_y \right] x^{(k+1)} = A^T y \end{aligned} \quad (13)$$

5 Simulation Results

We use an accurate electromagnetic simulation software package, which uses the FDTD algorithm[8], to generate data. For the simulation presented in this paper, a flat air/soil interface is used; the soil was modeled as lossless, non-dispersive, and has uniform relative permittivity ($\epsilon_{soil} = 2.6$). A plastic mine was buried in the soil, with relative permittivity of 2.9. Both the soil and the mine's relative permeabilities are 1. The mine's upper surface is at a depth of 10cm below ground, and the mine is 6 cm thick, with a diameter

of 10cm. The region of interest is a 20cm by 20cm square, which is 5cm below the ground surface(see Fig. 1).

In the computation experiments, the full nonlinear simulation code is used to generate collected signals for two conditions: the case where the mine is present, and the case where only soil is present. The signals collected when no mine is present consists entirely of the ground reflection; these signals are used to subtract the ground reflection from the signals collected when the mine is present, leaving primarily the signals due to backscattering from the mine. Fig. 3 shows the signal collected by the middle receiver(after subtracting

Figure 3: Data collected by the middle receiver

the ground reflection signal) and the signal predicted by the discrete Born approximation model. Fig. 4 and Fig. 5 illustrate how the data collected by different receivers decays with the receiver's offset from the central axis. To obtain the measured data, we corrupted the simulation outputs with 10dB of additional white Gaussian noise. The resulting signals were processed using the algorithms of the previous section to obtain the buried object profiles.

The reconstruction results are shown in Fig. 6. The total variation method with no orientation preference($\alpha = 1$) produces visually better results than the Tikhonov regularization, but lacks horizontal resolution. The total variation method with orientation preference($\alpha = 1.8$) gives the best reconstruction result, which significantly improves the horizontal resolution compared to the other two methods.

6 Conclusion

We have developed an efficient reconstruction algorithm for weak-contrast buried objects based on the Born approximation model and edge-preserving regularization techniques. We have illustrated the advantages of this algorithm for an example including buried plastic mines imaged using ground-penetrating radar arrays.

The particular model used in this paper made important simplifying assumptions such as a flat air/soil interface and lossless, non-dispersive soil propagation. Our current research directions are exploring alternatives for incorporation of these effects into the reconstruction algorithms.

ABSTRACT

This paper attempts to investigate hypothesis test performance in mine detection, based on numerically simulating the wideband scattering of experimentally measured GPR signals by realistic, dispersive soil interfaces. We employ a 2D finite difference time domain (FDTD) method to analyze the delay and amplitude characteristics of ground-scattered waves as a function of roughness parameters. In addition, we apply binary hypothesis tests to the signals obtained using physics-based signal processing techniques to investigate the presence of the target at certain depth. We quantify the detection performance in terms of the spatial distribution of transmitter and receiver.

INTRODUCTION

Detecting buried dielectric targets—such as nonmetallic antipersonnel mines—with ground penetrating radar (GPR) is important and difficult, because the dielectric constant of nonmetallic mine targets are similar to those of the surrounding soil, and because their size is comparable to the thickness of soil layer above it. In addition, the soil dielectric constant may not be well characterized, and the ground surface will usually be rough, often with roughness of the order of the target burial depth. We simulate the effects of random rough ground surface on the GPR signal using multiple Monte Carlo runs of 2D TM FDTD calculations. A typical bistatic geometry (Fig. 1a) is used along with a measured excitation signal generated by the Geo-Centers TEMR GPR antenna (Fig. 1b).

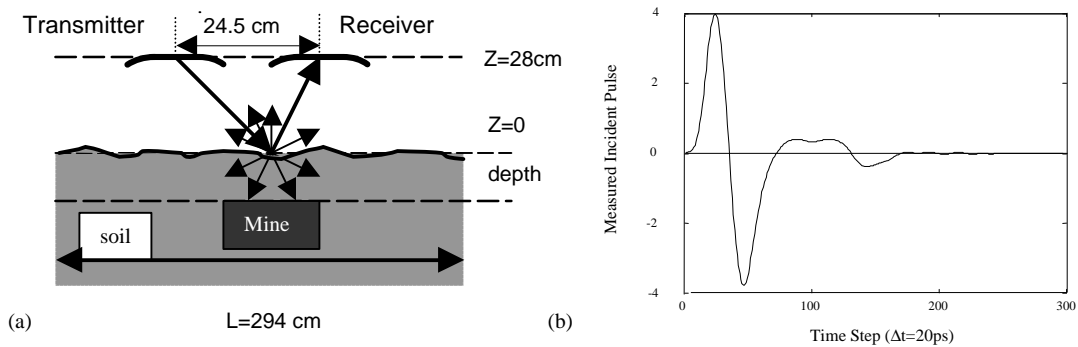

Figure 1: (a) Rough surface computational geometry; (b) incident measured waveform

In the FDTD code, the time step is $\Delta t = 20$ ps and $\Delta = 1.22$ cm. Simulations are done for 500 surface realizations with and without a mine target at various depths below the nominal surface level for a variety of roughness statistics. The probability density function for the height and the surface profiles spectrum are both assumed Gaussian [1,2]. The soil model is Puerto Rican clay loam with 10% moisture and 1.4g/cc density, with average dielectric constant $\epsilon' = 6.2$ [3].

SIGNAL AND CLUTTER SEPARATION MODELING AND PROCESSING

The background averaging procedure is used to remove the ground clutter signal, when the target is small, shallow, and of low contrast, [2,4]. The cross-correlation function and relative scaling factor are introduced. The cross-correlation function between reference signal ‘ f ’ and any realization signal ‘ i ’ is:

$$C_{fi}(m) = \sum_{n=1}^{N-|m|} S_f(n) S_i(n+m) / \left(\sqrt{\sum_{n=1}^N |S_f(n)|^2} \sqrt{\sum_{n=1}^n |S_i(n)|^2} \right) \quad \text{for } m > 0 \quad (1a)$$

$$C_{fi}(m) = C_{if}(-m) \quad \text{for } m < 0 \quad (1b)$$

The relative scaling is defined as:

$$A_i = \sqrt{\sum_{n=1}^N |S_i(n)|^2} / \max(C_{fi}) \quad (1c)$$

Where $i = 1, 2, \dots, M$ is the rough surface realization index, M is the size of Monte Carlo sample, and N is the total number of time steps. Compared to the scaling definition that is relative to the signal energy, the background averaging process will end up with a better output signals using the definition in (1c). The nominal background signal is found by aligning the time index of its maximum cross-correlation $m_{\max i}$, scaling by A_i , and averaging. To reduce ground clutter, this nominal background signal is again shifted back by $m_{\max i}$, scaled by A_i , and subtracted from each S_i signal. These background-subtracted signals are once again realigned to the expected target position [2,4]. Fig. 2 shows the average of 500 aligned background-subtracted signals (solid line) and the ± 1.0 standard deviation confidence interval (dotted lines).

SIMPLE BINARY HYPOTHESIS TESTING

We simplify the mine detection problem to be: whether there is mine at certain depth with acknowledgement of the roughness of the surface. Each of the two answers corresponds to a hypothesis:

H_1 corresponds to the presence of a target (*i.e.* mine presence)

H_0 corresponds to no target (*i.e.* no mine)

Applying the likelihood ratio test, which is derived to be [5]:

$$\frac{1}{2} (\mathbf{R}^T - \mathbf{m}_0^T) \mathbf{Q}_0 (\mathbf{R} - \mathbf{m}_0) - \frac{1}{2} (\mathbf{R}^T - \mathbf{m}_1^T) \mathbf{Q}_1 (\mathbf{R} - \mathbf{m}_1) \underset{H_0}{\overset{H_1}{<}} \text{threshold} \quad (2a)$$

where \mathbf{R} , \mathbf{m}_0 , and \mathbf{m}_1 are vectors with N elements, \mathbf{Q}_0 and \mathbf{Q}_1 are $N \times N$ covariance matrices. \mathbf{R} represents the individual background-subtracted (target) signals. \mathbf{m}_1 is the average of background-subtracted (target) signals shown in Fig. 2, and \mathbf{m}_0 is the average of unaligned no target (clutter) signals, *i.e.* the no-target signal. The covariance matrices \mathbf{Q}_0 and \mathbf{Q}_1 are the inverses of the diagonal matrices of standard deviations of the target and clutter signals. 100 out of 500 target signals and 100 out of 500 clutter signals are grouped as test signals. The mean signals \mathbf{m}_0 and \mathbf{m}_1 , and standard deviations are obtained from the remaining 400 target signals and 400 clutter signals. The likelihood ratio test is applied to each individual test signal associated with a set of trial thresholds.

Sequentially, the probability of *false alarm* P_F (i.e. we say the target is present when it is not) and the probability of detection *alarm* P_D (i.e. we say the target is present when it is) are obtained. The sample performances of the detections for several rough surfaces with Gaussian height S_c and correlation length L_h parameters, and depths are shown in Fig. 3.

As the depth of buried mine increases within some region and the surface becomes more flat, the performance improves. By relating signals associated with certain depth to several mean signals for different depths, it has been found that the best performance always occurs for the correct depth estimate. An example is shown in Fig. 4. The test signals with depth 8.5cm were related to the mean signals belonging to the same roughness group. Thus, the correct target depth will be obtained by testing sample signals with stored mean signals for a given ground surface roughness. Interestingly, the ROC curves for close but not exact depths are worse than those for much deeper or shallower depth estimates.

The previous results are based on the geometry shown in Fig. 1a, with the target centered beneath the transmitter-receiver (TR) pair. As the pair moves away from the mine, the test performance degrades. Also, the amplitude of the mean target signal will drop, as shown in Fig. 5. However, the combination of several TR views improves the detection performance. Although performance increases with the number of views, the combination of three TR positions, each spaced 10 spatial steps apart (i.e. $10 \times 1.22 \text{ cm} = 12.2 \text{ cm}$) to the left and right, appear to give excellent results. The improvements of using three and five bistatic TR pairs are shown in Fig. 6.

CONCLUSION

Using the physics-based signal processing, the background-subtracted and clutter signals have been analyzed. Applying binary hypothesis tests on these signals, the mine can be localized at certain depths even under rough ground surfaces. Furthermore, the detection performance is improved by combining multiple TR pair combinations.

Clutter Modeling: Rough Ground Surface

Outline

- Necessity of modeling soil background environment in mine detection
- Frequency domain discrimination of non-metallic target shapes for smooth/rough ground
- Dispersion in the time domain
- Monte Carlo FDTD modeling of rough ground effects.

Numerically Modeling EM Wave Propagation in Soil to Aid Sensor Design

- Only with knowledge of the environment surrounding mines can efficient advanced sensors be developed.
- Soil environment is extremely varied and inhomogeneous.
- Propagation is quite different in different soils.
- Numerical modeling is the only viable means of testing candidate sensing concepts on the wide variety of conditions.
- Simple flexible models that capture the essential electrical characteristics are best.
- Visualization of wave propagation assists in sensor synthesis.

Conclusions

- Rough ground surface is the main difficulty with GPR detection/discrimination of mines
- For a single frequency, extraction of target signal from rough ground scattering is extremely difficult, even with ideal detectors
- Increasing sensing frequency improves detection resolution, but also greatly increases clutter signal
- Dispersion is an important effect for time domain modeling, and can be included with supplemental difference equation.
- Monte Carlo FDTD modeling of rough scattering indicates wide variety of signal corruption: time shifting, scaling, distortion, which depend considerably with roughness statistics
- With shifting and scaling, expected value of ground scattered signals can be well characterized

Physics-based forward models for mine detection signal processing

Carey Rappaport and Eric Miller
Northeastern University
Boston, MA 02115

To effectively detect non-metallic buried antipersonnel mines, sophisticated signal processing that identifies possible target anomalies in the presence of widely varying artificial and environmental clutter are essential. These methods rely on precise, yet robust models of wave propagation and field distribution. The competing requirements of flexibility of including inhomogeneities in background soil and ground surface, wide frequency ranges for sensing, and computational efficiency demand careful model specification.

A key issue in this effort is the synthesis of computational forward models that are well suited for the processing task at hand. Ideally these models should be explicitly parameterized in terms of the information one wishes to extract from the data. If the goal of the algorithm is the determination of the locations, shapes, and electrical properties of an object in the receiver's field of view, then it is generally best to employ a model in which these parameters appear explicitly. In particular, for such a problem a T matrix based method would be ideal as this class of forward model exploits heavily the geometry of the scattering objects. However, T matrix methods model inhomogeneities poorly. Alternatively, a high dimensional finite difference scheme could include a rough ground surface and buried rocks, but is less effective for target recognition since the sampling points have no easily defined relationship to the objects' geometric characteristics.

In addition to the parameterization of the model, it is also of import that the model possess low computational complexity. Generally, any inversion scheme requires repeated use of the forward model to evaluate the suitability of the current estimate and determine how best to improve this guess. When the number of such evaluations is of the order of hundreds or thousands, clearly it is critical that the underlying model be as fast as possible. Continuing the previous example, because the T matrix approach admits a recursive implementation for multi-object scattering problems, in general it is far more efficient than a finite difference or finite element approach which requires the solution of a large system of linear equations.

Mine Detection Using a Handheld Parabolic Antenna: Analysis of Experimental Data

Bo Yang and Carey Rappaport
Center for Subsurface Sensing and Imaging Systems
Northeastern University
Boston MA

PIERS, Cambridge MA, July 5 2000

Outline

- Novel parabolic mine detector
- Result of the 2-D FDTD simulation of parabolic reflector in mine detection
- Experiment and data analysis
- Conclusion

Demining MURI Supported by ARO

Problem: Rough Ground Surface is Greatest Contributor to GPR Clutter

- For standoff GPR detection of small antipersonnel mines, the largest scattered signal comes from the ground surface.
- In the real world, the ground is never flat, the soil type is never known exactly, and the height of the antenna is never fixed.
- This clutter can be reduced by:
 - Time gating
 - Signal processing (matched filtering, deconvolving)
 - Spatially separating target/clutter signals

Advantages of Plane Wave Excitation Over Currently Used Mine Detection Technology

- Specular reflection from the ground depends only on incidence angle, frequency content, and wave polarization, not position or source.
- For flat ground with non-normal incidence, reflection scatters in forward direction.
- Transmitted waves obey Snell's law, the wavefronts remain parallel, and the signal arrives at a given target with the same delay and attenuation due to soil.
- Plane wave excitation generates scattered signals that are easier to distinguish from rough surface clutter.

Paraboloidal Reflector Transmitter

- Parabolas convert circular waves to plane waves.
- GeoCenters, Inc. TEMR wideband antenna element (700 MHz to 1.3 GHz) used to feed offset parabola.
- Collimated beam in the nearfield, is a (non-uniform) plane wave across its aperture.
- Trade-offs between reflector size and grazing incidence angle, -- and height above ground versus forward look -- must be made.

Novel Forward-Looking “Handheld” AP Mine Detector with Plane Incidence Wave Excitation

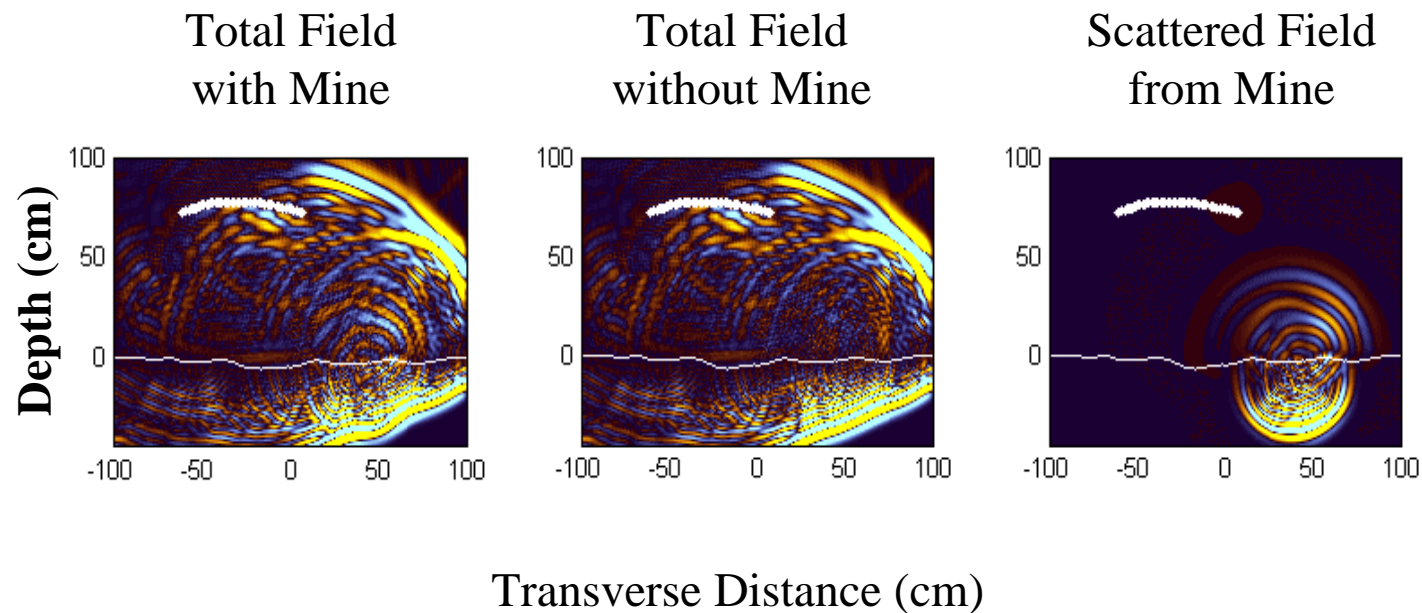

Offset Paraboloïd Ray Paths

Multistatic Receiving Array

- Collimating transmitter is coupled with a four element receiving array.
- 2 X 2 array gives four times the received power of a monostatic radar, as well as temporal focusing left to right and forward to back.
- By comparing time differences of received scattered signals, approach and localization information can be extracted.
- By measuring overall time delay, depth of burial information is available.

Down Track Position (in.)

Data Analysis

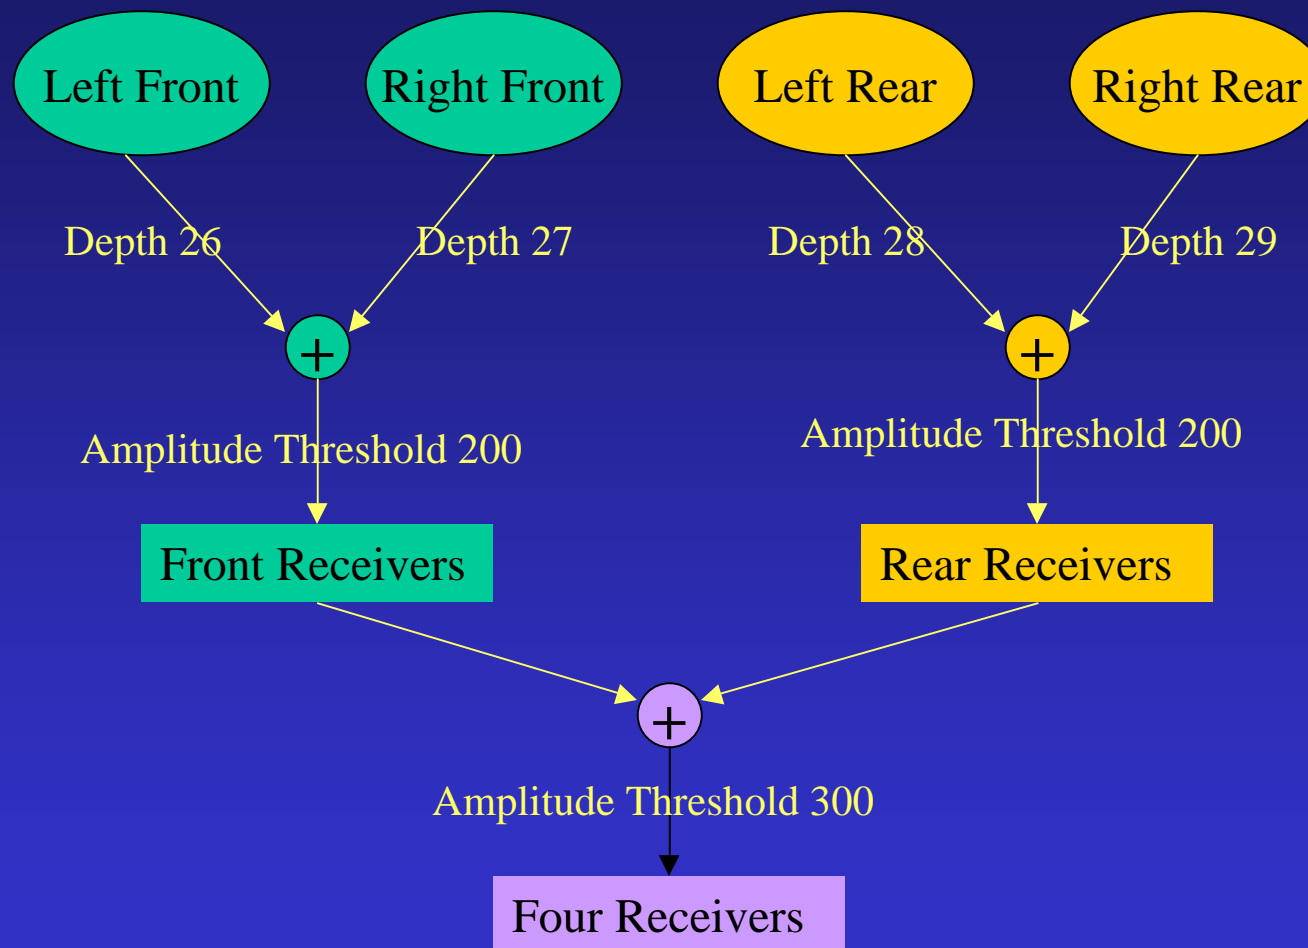

1. Remove soil clutter from the total field to obtain mine signals.

- Ideal ground signal
- Total average ground signal
- Moving average ground signal

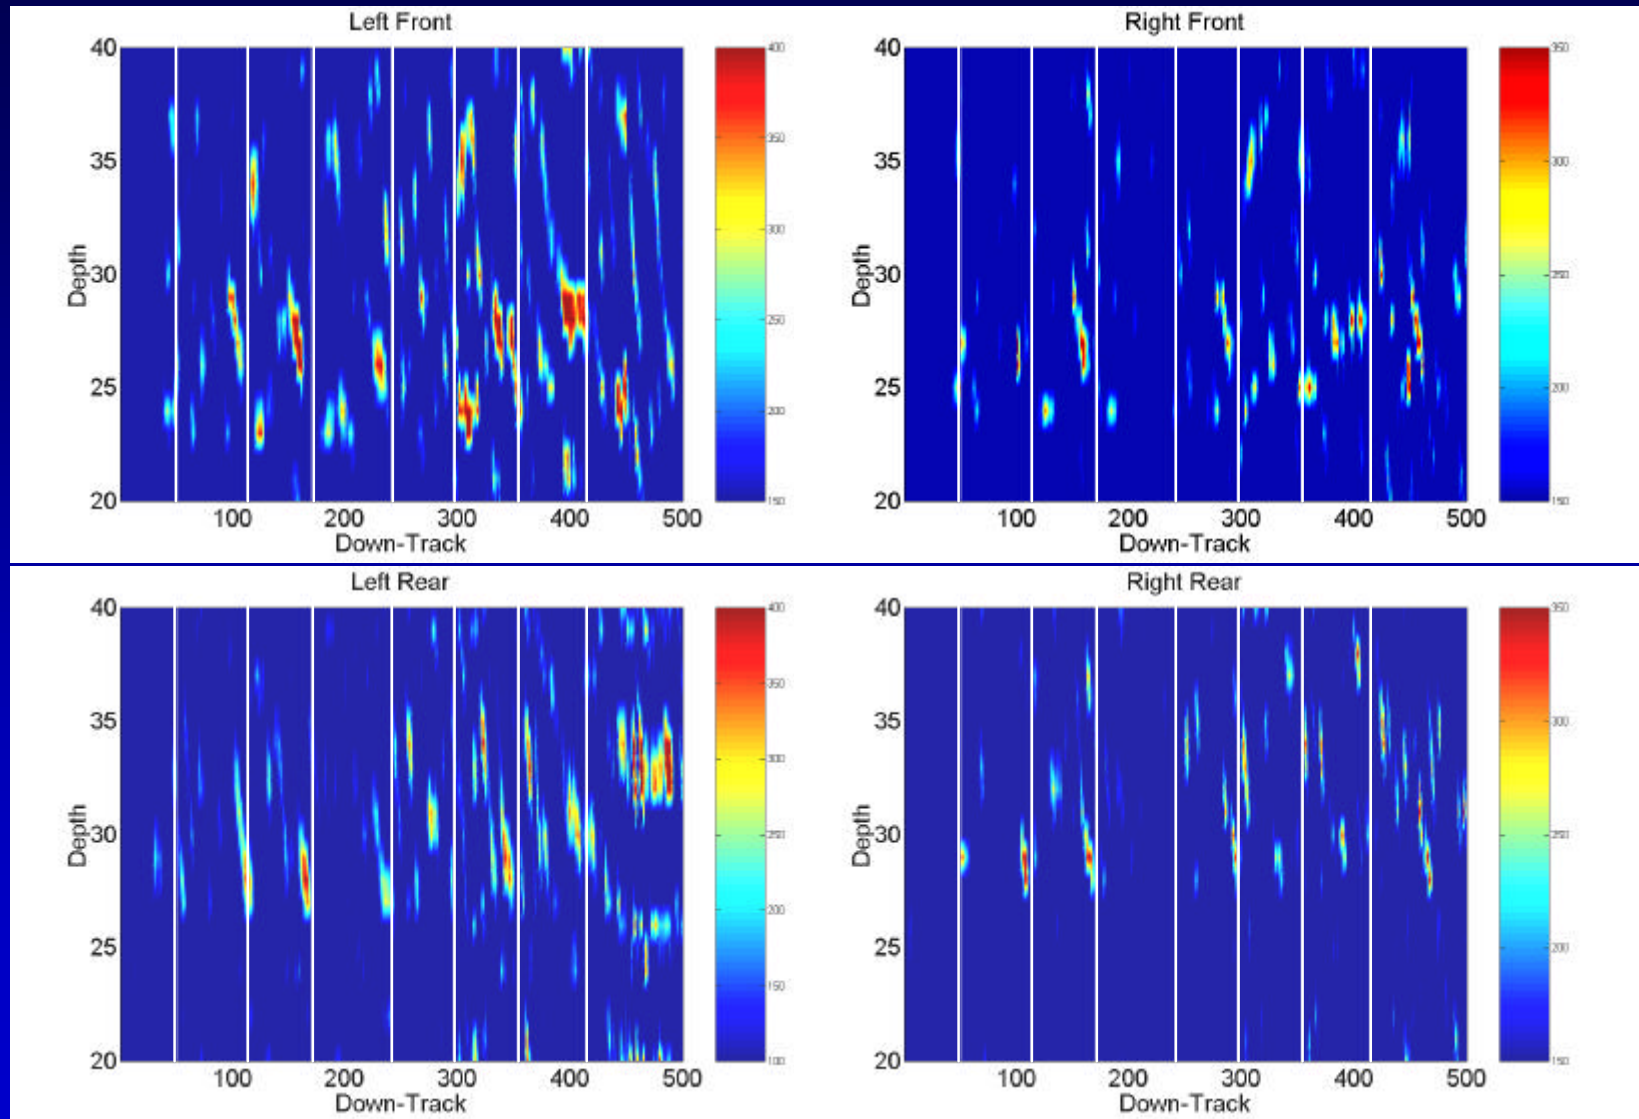

1. Evaluate the performance of different receivers.

2. Synchronize the mine signals at different receivers to obtain strong mine signals.

Mine Signals Synchronization and Summation

Mine Signals

Low Intensity Feature with Distinctive Shape (to be exploited with future processing)

Mine Signals at Specific Depths

Summation of Four Receivers

Factors that Effect Performance

- Mines are of different types.
- Mine burial depth and orientation vary.
- Soil moisture and ground surface roughness change along the track.
- Radar pulse width and sensing time window are limited.

Conclusions

Initial experiments indicate that the parabolic antenna mine detector performs very well in detecting shallow buried nonmetallic mines in relatively dry soil.

The sensor gives strong mine signals at locations that agree with the locations of the buried targets with only a few false alarms and detection failures.

Multistatic Receiving Array

- Collimating transmitter is coupled with a four element receiving array.
- 2 X 2 array gives four times the received power of a monostatic radar, as well as temporal focusing left to right and forward to back.
- By comparing time differences of received scattered signals, approach and localization information can be extracted.
- By measuring overall time delay, depth of burial information is available.

Conclusions

- Plane wave excitation decreases scattering confusion.
- Forward looking radar takes advantage of specular ground reflection.
- Offset Paraboloid creates unblocked forward propagating plane wave.
- FDTD predicts distinct scattered and surface reflected signals, even for rough surfaces.
- Experimental results indicate that even small, nonmetallic AP mines are detectable in *sand*

An Efficient Mur-Type ABC for Lossy Scattering Media

Outline:

- Motivation
- Contrasts of Mur and Mur-Type formulations
- Numerical Code Implementation
- Case Models
- Conclusions

Motivations:

- **Mur-Type ABC vs. PML:**
 - **PML:**
 - Multilayered PML loss coefficients must be recomputed at each sublayer for lossy media.
 - Code becomes increasingly complex at multiple boundary limits for 2-D or 3-D geometry.
 - **Mur-Type ABC:**
 - ABC computations are single-celled at all bounding grid points.
 - Only minor adjustments to the code are required as the dimensions of the computational space are selected.

Mur-Type ABC Contrast #1

- Ampere's Law has added conductivity term for lossy soil:

$$\nabla \times \vec{H} = \epsilon_o \frac{\partial}{\partial t} \vec{E} + \sigma \vec{E}$$

Propagation in Soil is Frequency Dependent

$$k(f) = b(f) - ja(f) = \frac{2\pi f}{c} \sqrt{\epsilon'(f) - j \frac{\sigma(f)}{2\pi f \epsilon_0}}$$

**Neglecting the frequency
dependence gives inaccurate results.**

 $\epsilon_0, S_{\text{soil}}, S_1$ and frequency

Mur-Type ABC Contrast #2

- Wave equation for boundary condition has additional term for conductivity:

$$\left[\partial_x^2 + \partial_y^2 + \partial_z^2 + \omega^2 \mu_o \epsilon_o \left(\epsilon' - j \frac{\sigma}{\omega \epsilon_o} \right) \right] E(\omega)_{x=0} = 0$$

Mur-Type ABC Contrast #3

- Pre-approximation equation has conductivity term added to Mur approximation:

$$\text{Using: } \tilde{S}_y = \frac{\partial_y}{j\omega}, \quad \tilde{S}_z = \frac{\partial_z}{j\omega}, \quad \mu_o\epsilon_o = \frac{1}{c^2}$$

$$\partial_x = \left(\frac{j\omega\sqrt{\epsilon'}}{c} \right) \left[1 - j \frac{\sigma}{\omega\epsilon'\epsilon_o} - \frac{(c\tilde{S}_y)^2}{\epsilon'} - \frac{(c\tilde{S}_z)^2}{\epsilon'} \right]^{1/2}$$

Mur-Type ABC Contrast #4

- New approximation retains extra term to account for conductivity:

$$\left[\partial_x - \frac{\sqrt{\epsilon'}}{c} j\omega - \frac{\eta_s}{2} \sigma(\omega) \right] E(\omega)_{x=0} = 0 \quad \text{where : } \eta_s = \sqrt{\frac{\mu_o}{\epsilon' \epsilon_o}}$$

Mur-Type ABC Contrast #5

- Conversion to FDTD is accomplished using a Z-transform:

$$\left[\partial_x - \frac{\sqrt{\epsilon'}}{c} \left(\frac{1 - Z^{-1}}{\Delta t} \right) - \frac{\eta_s}{2} \sigma(Z) \right] E(Z)_{x=0} = 0$$

- Where the conductivity is represented by the Pade' approximant:

$$\sigma(Z) = \frac{b_0 + b_1 Z^{-1} + b_2 Z^{-2}}{1 + a_1 Z^{-1}}$$

Mur-Type ABC Contrast #6

Second Order Approximation:

$$\frac{\partial_x}{j\omega} = \frac{\sqrt{\epsilon'}}{c} \left[1 - \frac{1}{2} \left(j \frac{\sigma}{\omega \epsilon' \epsilon_o} + \frac{(c\tilde{S}_y)^2}{\epsilon'} + \frac{(c\tilde{S}_z)^2}{\epsilon'} \right) \right]$$

$$\left[\frac{\sqrt{\epsilon'}}{c} j\omega \partial_x - \frac{\epsilon'}{c^2} (j\omega)^2 - \frac{1}{2c^2 \epsilon_o} j\omega \sigma - \frac{1}{2} (\partial_y^2 + \partial_z^2) \right] E = 0$$

For 2-D $E_z(x, y)$:

$$\left[\frac{\sqrt{\epsilon'}}{c} \partial_x - \frac{j\omega \epsilon'}{c} - \frac{\sigma \mu}{2} \right] E_z + \frac{\mu}{2} \partial_y H_x = 0$$

Numerical Code Implementation of Second-Order Approximation

The Z-Transform of the second-order Mur-Type approximation is incorporated into FDTD code with the following guidelines for stability:

- All spatial-derivatives (d/dx) are backward-averaged in time.
- All time-derivatives (d/dt) are forward-averaged spatially.
- All non-derivative terms are forward-averaged spatially.

Numerical Implementation of Second-Order Approximation

$$E_{x+1}^{n+1} = -1/(1 + T + B_0 S) \left[E_{x+1}^n (-1 + T + b_0 S) \right. \\ + E_{x+1}^n [(1 + a_1) - T(1 - a_1) + S b_1] \\ + E_x^n [-(1 + a_1) - T(1 - a_1) + S b_1] \\ + E_{x+1}^{n-1} [a_1 - T a_1 + S b_2] \\ + E_x^{n-1} [-a_1 - T a_1 + S b_2] \\ \left. - \frac{S}{\Delta} \frac{\partial (H_{x+1}^n + a_1 H_{x+1}^{n-1} + H_x^n + a_1 H_x^{n-1})}{\partial y} \right]$$

$$T = \frac{\delta \sqrt{\epsilon'}}{c \Delta t} = \frac{1}{R'} \text{ and } S = \frac{\eta_0 \Delta}{2 \sqrt{\epsilon'}}$$

Conclusions

- Additional conductivity considerations can satisfy the wave equation more appropriately for boundary conditions in lossy media.
- Improved performance by reducing back-scatter from ABC to less than 1% for normal incidence.
- Mur-Type calculations rely on a single-layer boundary thickness: simple, robust, fast.

Quantifying the Effects of Different Rough Surface Statistics for Mine Detection Using the FDTD Technique

ABSTRACT

The finite difference time domain technique, FDTD, is used to calculate the scattered field in the near zone from one-dimensional random rough surfaces. Different statistics for the random surface will be assumed in this work. First, the random rough surface will be characterized by one-scale roughness with Gaussian distribution for the heights and Gaussian auto-correlation function. In the second part, the surface will be assumed to have two-scale roughness (composite) with the same Gaussian statistics as before. The statistics of the scattered fields are calculated in this work using Monte Carlo simulations. Numerical results comparing scattered fields from one-scale roughness and two-scale roughness are shown. The results obtained indicate that the distortion in the scattered signals is primarily due to the small-scale roughness while the two-scale roughness (composite) causes more time delay in the scattered signals. Different rough surface parameters will be used to quantify their effect on the statistics of scattered signals.

Key words: rough surface statistics, composite rough surface, scatter, FDTD, mine detection.

1. INTRODUCTION

A realistic rough ground does not necessarily have a single scale of roughness. In fact, it is more accurate and practical to assume that the rough surface has multi-scale roughness. An investigation about the effect of roughness scale on the statistics of the scattered field is conducted in this work. The probability density function of the surface heights is assumed to be Gaussian for all scale-roughness. The surface profile spectrum (autocorrelation function) is also assumed to be Gaussian. For a composite rough surface (two-scale roughness), the small-scale random rough surface will be imposed on the large-scale rough surface given that each single-scale roughness is generated independently. For the large-scale roughness surface, the correlation length is assumed to be much larger than it in the small-scale roughness surface. This enforces the length of the one-dimensional surface to be sufficiently large, at least ten times the larger correlation length. The statistics of the scattered signals are computed in this work using Monte Carlo simulations. The effect of surface roughness parameters, root mean square

heights and slopes, and surface statistics assumptions on the scattered signals will be investigated as well. The geometry of the problem is shown in Fig. 1a, in which the transmitter and receiver antennas are located above the rough soil ground. Fig. 1b shows the magnitude of the measured incident pulse used in this work.

2. FORMULATIONS

2.1 Metric Measure for Signal Statistics

Three factors will be considered here as metric measure for the signal statistics. They are the average time shift, the average scaling, and the average distortion of the signal. The Monte Carlo simulations and the cross-correlation function will be used to calculate these statistics.

2.1.1 Cross-Correlation Function

The cross-correlation function, by definition, indicates the inter-dependence of the values of two different processes at two different times. The normalized cross-correlation functions between signal ' f ' and signal ' i ' is given by

$$C_{fi}(m) = \sum_{n=1}^{N-|m|} S_f(n) S_i(n+m) / \sqrt{\sum_{n=1}^N |S_f(n)|^2} \sqrt{\sum_{n=1}^N |S_i(n)|^2}, \quad \text{for } m > 0 \quad (1a)$$

and,

$$C_{fi}(m) = C_{if}(-m), \quad \text{for } m < 0 \quad (1b)$$

The relative scaling will be defined as

$$A_i = \sqrt{\sum_{n=1}^N |S_i(n)|^2} / \sqrt{\sum_{n=1}^N |S_f(n)|^2} \quad (1c)$$

where, $i = 1, 2, 3, \dots M$, is the rough surface realization index, M is the size of Monte Carlo Sample (total number of generated random realizations for the rough surface). And N is the total number of time steps in each signal. The above definitions are pictorially described in Fig.2. Numerical illustrative examples for these definitions will be shown in section 3.

Fig.2a Signals S_0 and S_1 .

Fig.2b Signal S_1 shifted by τ .

Fig.2c S_1 scaled by A .

2.2 Rough Surface Characterization

The one-dimensional rough surface is described here by $z = f(x)$, where z is the height of any point on the surface. Since the rough surface is assumed to be random, two functions are needed to fully characterize it. They are the probability density function of the surface random heights and the autocorrelation function (surface profile power spectral density function).

2.2.1 Gaussian Random Rough Surfaces

Assuming that the random height of the surface has a Gaussian distribution with zero mean and standard deviation equal to σ_h , the probability density function of the height is [1]

$$p(z) = \frac{1}{\sigma_h \sqrt{2\pi}} \exp\left(-z^2 / 2\sigma_h^2\right) \quad (2)$$

Note that the statistical distribution of the height provides no information about the distances between the hills and the valleys of the surface, i.e., about the density of the surface irregularities [1]. Thus the rough surface can not be described uniquely by the probability density function of the surface height. Another function is needed to complete the description of the rough surface. This function is the autocorrelation function or its Fourier Transform, the surface profile power spectral density function. The autocorrelation function $R(x_d)$ gives the correlation between the random heights at two different points on the surface, x_1 and x_2 . It is defined by [1], [2]

$$R(x_d) = \frac{\langle f(x_1)f(x_1 + x_d) \rangle}{\sigma_h^2} \quad (3a)$$

where,

$$x_d = x_2 - x_1 \quad (3b)$$

For full correlation, $\lim_{x_d \rightarrow 0} R(x_d) = 1$, and for independence, $\lim_{x_d \rightarrow \infty} R(x_d) = 0$. Moreover, if the surface profile spectral density function $W(K_x)$ is given, then the auto-correlation function $R(x_d)$ can be obtained by the inverse Fourier Transform as

$$R(x_d) = \frac{1}{\sigma_h^2} \int_{-\infty}^{\infty} W(K_x) \exp(iK_x x_d) dK_x \quad (4)$$

Thus, the Gaussian joint probability density function for two heights on the surface, z_1 and z_2 , with zero mean and standard deviation σ_h is given by [1],[3]

$$p(z_1, z_2) = \frac{1}{2\pi\sigma_h^2 \sqrt{1 - R^2(x_d)}} \exp\left(-\frac{z_1^2 - 2R(x_d)z_1z_2 + z_2^2}{2\sigma_h^2(1 - R^2(x_d))}\right) \quad (5)$$

If the surface spectral density $W(K_x)$ is assumed to be Gaussian as [2]

$$W(K_x) = \frac{l_c \sigma_h^2}{2\sqrt{\pi}} \exp\left(-\frac{K_x^2 l_c^2}{4}\right) \quad (6a)$$

in which K_x is the surface profile wave number. Thus from (3), the auto-correlation function will also be Gaussian given by

$$R(x_d) = \exp\left(-\frac{x_d^2}{l_c^2}\right) \quad (6b)$$

Where l_c is the correlation distance for which $R(x_d)$ will drop to the value e^{-1} .

2.2.2 Composite Random Rough Surfaces (two-scale roughness)

It is very rare if not impossible to characterize a realistic rough ground soil by only one scale of roughness. In practice, the rough soil is composed of several roughness scales. In this work we will characterize the soil surface by two-scale roughness (composite surface). This two-scale roughness surface is composed of two single-scale independently generated surfaces. The first surface has small roughness parameters, root mean square height and correlation length, and the second surface has large-scale roughness parameters [4]. In other words, the correlation length in the large-scale surface should be at least ten times larger than the correlation length in the small-scale surface [4] and [5]. This requires the length of the 1-D rough surface to be sufficiently large, several correlation lengths. Examples of small-scale, large-scale, and composite rough surfaces are shown in Fig.3. The three random rough surfaces in Fig.3 are assumed to have zero-mean as shown in the small-roughness surface (upper trace). Both the large-roughness (middle trace) and composite surfaces (bottom trace) are shifted in this figure for the purpose of clarification.

Fig.3 Small ($\sigma_h=1\text{cm}$, $l_c=3\text{cm}$), large ($\sigma_h=3\text{cm}$ and $l_c=30\text{cm}$) and composite roughness surfaces

2.4 Monte Carlo Simulations

The Monte Carlo simulation is the process of taking the ensemble average of several independent random variables. The random variables here are the near fields scattered from several independently generated random rough surfaces. There are several methods to conduct Monte Carlo simulations for the scattered signals, in this work it will be defined as

$$\langle S \rangle = \frac{1}{M} \sum_{i=1}^M S_i \quad (8)$$

where S_i is the amplitude of the scattered near field signal from rough surface realization ' i '. Ideally M should be equal to infinity to assure the application of the central limit theorem. Thus, M will be chosen large enough and each rough surface realization will be generated independently using the computer random number generator.

3. NUMERICAL RESULTS

In all presented results in this work, the ground is assumed to be dispersive soil [6] and the scattered electric field is in the normal direction to the plane of incidence (TM polarization for 2D FDTD calculations). Moreover, the signal that propagates directly from transmitter to receiver has been removed from scattered signals. The nominal frequency of the incident signal is 1GHz (wavelength=30cm). The FDTD time step is $\Delta t=20\text{ps}$ and the space step is $\Delta=1.219\text{cm}$. Numerical results for the definitions of the metric measure for signal statistics, given in section 2.1, are shown in Figs.4-6. The amplitudes of the scattered signal from flat ground and from one rough surface realization

are shown in Figs.4a and 5a, respectively. The roughness parameters in these figures are $\sigma_h=3\text{cm}$ and $l_c=10\text{cm}$. Figs.4b and 5b show the normalized signals of Figs.4a and 5a according to the scaling definition of Eq. 1c. The cross correlation functions, given in Eq.1, for this one rough surface realization with the flat surface signal and for the flat surface with itself are shown in Fig.6a. Notice that the cross correlation function of the flat surface with itself is symmetric around the zero, which is not the case for the rough surface as shown in Fig.6a. Moreover, that there is a time shift τ_i between the flat and rough surface cross correlation functions. These parameters, scaling A_i and time shifting τ_i , will be obtained for each rough surface realization 'i' in the Monte Carlo sample and their average values will be calculated, as will be shown later in this section. Fig.6b shows the scaled and time shifted scattered signals of Figs.4a and 5a.

In Figs.7-10, different statistics for the scattered fields from small-, large-, and composite roughness surfaces, Fig. 3, will be shown. The roughness parameters for the small-scale surface are $\sigma_h=1\text{cm}$ and $l_c=3\text{cm}$, while they are $\sigma_h=3\text{cm}$ and $l_c=30\text{cm}$ for the large-scale surface. The composite surface is obtained by algebraically adding the small- and large- scale surfaces as explained in section 2.2.2. The obtained statistics for the scattered fields are based on the Monte Carlo simulations as given by Eq. 8. In this work, the size of each Monte Carlo sample is chosen to be 500 realizations. In Figs. 7, 8, 9 the histograms for the scaling and time shifting parameters are shown for the small-, large- and composite rough surfaces, respectively. In Fig.10a-c, the scattered signals from the flat surface are compared with the mean value of the scattered signals from these three rough surfaces. The signal scattered from the small-scale roughness surface, Fig10a, is more distorted than the one scattered from the large-scale roughness surface, Fig.10b. Almost no difference is observed in Fig.10b between the two signals. As a result the scattered signal from the composite surface is more distorted than the one scattered from the large-scale roughness surface, Fig.10c. Table 1 shows the comparison between the average values of the time shift and scaling values for these surfaces. As might be expected, large-scale roughness does not appreciably affect the average scaling, where small-scale roughness distorts and spreads the signal in time as well as space. The scaling for the composite surface is dominated by the small-scale roughness value. Interestingly, the similar average time shift for the two single scale roughness add for the composite surface.

The effect of different surface roughness parameters on the statistics of scaling and time shifting values is shown in Table 2. These results are for single-scale roughness surfaces. The first column pair of the table shows the surface roughness parameters, root mean square height and correlation length. The second column pair shows the average scaling and time shifting values of scattered signals. The results show that the time delay and scaling average values increase with the increase of the surface roughness. All these results are obtained using Monte Carlo simulations of 500-sample size each.

4. CONCLUSIONS

Signals scattered from the rough ground are received at the receiver with amount of distortion and time delay compared with those scattered from the flat ground. This amount of the signal distortion and the time delay depend primarily on the surface roughness. Moreover they depend on the roughness scale of the surface as it has been shown here that the surface small-scale roughness affects the amount of distortion while the surface composite surface affects the amount of time delay. The significance of this work is to fully understand the effect of different rough surface statistics on the scattered signals and consequently from the buried mines under these surfaces.

Analysis of Three Dimensional Scattering from Random Rough Surfaces with Buried Penetrable Objects for Mine Detection Applications

The analysis of scattering and transmission of electromagnetic waves in the presence of a random rough dielectric interface and in the nearfield of the sensing systems is a crucial step for subsurface object detection problems in general and landmine remediation applications in particular. Generally, this fully three dimensional problem must be treated numerically, however the calculation of the required fields using conventional techniques (e.g. moment method, finite elements, or finite differences) is a computationally intensive undertaking especially for large dielectric constants. The complexity of the problem dramatically increases upon inserting objects under the rough interface especially when these objects are penetrable. Therefore a fast and accurate computational technique is needed for such applications.

The integral equation-based Fast Multipole Steepest Descent Method (SDFMM), that was originally developed at the University of Illinois (UIUC), will be modified and expanded here to analyze this intensive scattering problem. The rough surface is assumed a random one characterized with Gaussian statistics for the height with zero mean. A single penetrable object is buried at less than one wavelength beneath the mean plane of the rough interface. The incident wave, which is located above the surface, is assumed to be a Gaussian beam that is carefully tapered to minimize surface edge excitations. The PMCHW (Poggio, Miller, Chang, Harrington, and Wu) integral equations are implemented in this work for three regions; air, soil, and buried object. Upon applying the appropriate boundary conditions of the electric and magnetic fields on the air-soil interface, four integral equations are obtained. Both the rough surface and the buried object are discretized into triangular patches. The moment method surface currents are approximated using the RWG (Rao, Wilton, and Glisson) vector basis functions. The interactions between the rough surface and the buried object are fully taken into account here. Thorough investigation will be conducted to test several approximations to ignore some of these interactions aiming to simplify the involved intensive calculations.

Results for the near field complex vectors will be shown. Monte Carlo simulations will be conducted to obtain the statistics of both scattered and transmitted near fields as functions of receiver position, frequency, and incident angle. This work can be extended to include several buried objects of different dielectric constants and/or perfectly conducting ones. The ultimate objective of this research is to analyze, understand and consequently to be able to differentiate between scattering from buried objects and scattering from rough surfaces, clutter in this case.

Analysis of Low Grazing Angle Scattering from Composite Random Rough Surfaces Using the Steepest Descent Fast Multipole Method

The Steepest Descent Fast Multipole Method (SDFMM), a fast multipole inspired integral equation solver for quasi-planar structures, has been used successfully to analyze low grazing angles (LGA) scattering from perfectly conducting rough surfaces. As demonstrated in our previous work, at LGA the length of the finite simulated surface should be at least ten times larger than the width of the surface to adequately project the incident beam onto the surface. As a result, the number of the moment method surface current unknowns becomes excessively large. The SDFMM has been successfully and efficiently used to solve for more than a million surface current unknowns. In our previous work, the random rough surface was assumed to have a single scale roughness with Gaussian statistics. In reality, many rough surfaces exhibit multi-scale roughness, e.g. ocean like surfaces. In this work, we assume that the rough surface is characterized by two-scale roughness, i.e., two root mean square heights and correlation lengths characterize the surface. The rough surface is still assumed to adhere to Gaussian statistics for both the random heights and the auto-correlation functions. The small- and large-scale random surfaces are independently generated using the random Gaussian generator. The composite two-scale surface is obtained by imposing the small-scale surface on the large-scale one. The incident wave is assumed to be a Gaussian beam with incident angle equal to 80 degrees from the normal to the surface and the rough surface is assumed to be perfectly conducting. The goal here is to investigate the effect of the small-scale roughness versus the large-scale roughness on the RCS at low grazing angles. Monte Carlo simulations are used to calculate both the coherent as well as the incoherent RCS as function of the scatter angle. As shown before, for single-scale rough surfaces, the RCS has a peak in the specular direction at LGA. There are still several studies related to the LGA scattering phenomena that need an efficient, fast and accurate algorithm such as the SDFMM to be solved.

Modeling Clutter from Random Rough Ground for GPR Subsurface Sensing Applications

Scattering of electromagnetic waves from two-dimensional penetrable rough surfaces (3-D scattering) with different characteristics will be presented here. The integral equation-based fast algorithm, Steepest Descent Fast Multipole Method, will be used to analyze this intensive computational problem. The objective is to investigate the scattering phenomena of electromagnetic waves from typical Bosnian, Puerto Rican, and A.P. Hill soils. Soil moisture level, frequency band and surface roughness parameters are considered major factors that affect the scattered fields. For example, the range of volume moisture level in a typical Bosnian soil will be chosen from 3.8 to 25.3% for a frequency range 600Mhz-2Ghz. Thus the relative dielectric constant will range approximately from 3 to 10 and from 0.04 to 1.3 for the real and imaginary parts, respectively. As well known, for larger soil water content, the relative dielectric constant becomes larger, and as a result the problem becomes more computationally expensive. Different soil samples from Puerto Rican clay loam and A.P. Hill, Firing Point will be used in this work as well. The rough surface is characterized with Gaussian statistics for the random heights and also for the auto-correlation function. The roughness parameters (root mean square height and correlation length) are chosen to be in the moderate roughness range for the current application. For example, the root mean square height will range from 0.1 to 0.2wavelength and the correlation length will range from 0.5 to 1.5wavelength. The scattered near field E-patterns of an incident Gaussain beam will be calculated at different locations above the dielectric interface. The receiver locations are chosen to simulate GPR measurement protocols. Moreover, the transmitted E-patterns will be computed at locations below the rough dielectric interface.

The goal of this paper is to fully understand the effect of different soil properties on the scattering phenomena as an *a priori* phase of investigating scattering from buried mines under the same types of soil.

Statistics of Electromagnetic Near Fields Scattered from 3-D AP Mines Buried under Random Rough Surface Calculated Using the Steepest Descent Fast Multipole Method (SDFMM)

Abstract

The Steepest Descent Fast Multilevel Multipole Method (SDFMM) is used to analyze the distorting effects of random rough ground surfaces on scattered electromagnetic waves from buried *TNT* mines. The SDFMM method is an integral equation-based fast algorithm that is well suited for two-dimensional penetrable rough surfaces (3-D scattering) in the frequency domain, and it is used to calculate the unknown surface currents on both the rough ground and the buried target as well. In this study all interactions between the rough interface and the buried target are taken into account. The scattered near field E-patterns of an incident Gaussian beam are calculated at different locations above the mean plane of the dielectric rough interface. The receiver locations are chosen to simulate GPR measurement protocols. The dimensions and burial depth of the *TNT* mine are smaller than the free space wavelength with material slightly different from the surrounding soil. The average and the standard deviation of the scattered fields for just the target are calculated and results showed that the presence of the rough interface tremendously distorts the target signal even for the small roughness parameters. Moreover, results showed the degradation of signal as the *TNT* mine is located away from incident beam. This knowledge can significantly contribute to inventing better sensing systems for less false alarm detection strategies.

1. Introduction

The integral equation-based Steepest Descent Fast Multipole Method (SDFMM), that was originally developed at UIUC [1], [2], has been modified to handle the AP-mine detection application as shown in Fig. 1. The significant potential of the SDFMM code is that it calculates the unknown moment method surface electric and magnetic currents on the scatterer in a dramatically fast, efficient and accurate manner. The random rough ground surface was characterized with Gaussian statistics for surface height and for surface autocorrelation function [3]. New formulations of integral equations were obtained and presented in [4]. These new formulations had taken into account all interactions between the rough surface interface and the buried *TNT* mine.

Figure1. Cross section of 2-D rough surface ground with 3-D object buried under the interface.

As an *a priori* phase, the SDFMM was used to analyze the distorting effects of random rough ground surface alone (no buried targets) on the scattered and transmitted electromagnetic waves as presented in [5]. Two well-measured loamy soils [6]: Bosnian and Puerto Rican clay loam were investigated, each with a variety of surface roughness. This study is important in understanding the effects of different soil properties before investigating scattering from buried targets. A specialized fast algorithm was necessary, since multiple calculations of this realistic, but computationally intensive, model were needed for many different realizations of surface roughness. The scattered and transmitted nearfield E-patterns of an incident Gaussian beam [7] were calculated at different locations above and below the mean plane of the dielectric rough interface. The receiver locations above were chosen to simulate GPR measurement protocols. The obtained numerical results showed that the scattered field undergoes more distortion than the transmitted field from both soil types. Moreover, the transmitted fields into the higher dielectric constant Puerto Rican soil experienced more distortion than those transmitted into Bosnian soil [5].

Due to the observed distorting effects of the random rough surface in [5], Monte Carlo simulations are needed to estimate the statistics, average and standard deviation, of the AP-mine signature. The SDFMM has been modified to calculate the fields scattered from a shallow *TNT* mine, buried under the two-dimensional random rough ground. The

buried target is assumed to have size and burial depth comparable to the free space wavelength λ_0 . The scattered electric fields from the rough ground with the buried target are calculated in the near zone and their complex vector average over many rough surface realizations are computed. The target signature was obtained by subtracting the electric fields scattered from the rough ground only from those scattered from the ground with the buried *TNT* mine. The average and standard deviation of the electric fields are calculated as

$$Average = \left| \frac{1}{M} \sum_{i=1}^M \bar{E}_i \right| \quad (1)$$

$$STD = \sqrt{\frac{1}{M} \sum_{i=1}^M |\bar{E}_i|^2 - \left| \frac{1}{M} \sum_{i=1}^M \bar{E}_i \right|^2} \quad (2)$$

where, \bar{E}_i represents the complex vector electric field scattered from the i^{th} rough surface realization where $i=1, 2, \dots, M$, where the size of Monte Carlo set (M) is assumed to be 65 in all results here.

2. Numerical Results

Excellent agreements are obtained upon comparing the modified SDFMM computer code with other published techniques. In our previous work [4], the SDFMM code has been validated with the SMCG method (sparse canonical conjugate gradient method) where the scatterer is a PEC sphere buried under a random rough surface and very good agreement is presented. More validations of the SDFMM code are presented in this section; first, the SDFMM code is used to compute the bistatic scattering cross section of penetrable sphere with dielectric constant ($\epsilon_r = 1.75 - i0.3$) and radius ($a = 0.2\lambda_0$) due to an incident plane wave on the sphere as shown in Fig. 2. The scatterer is just the penetrable sphere immersed in air (no rough surface) and only the MoM part of the SDFMM code is used. The comparison shows very good agreement between the MoM part in the SDFMM code and both the Mie and MoM solutions published in Medgyesi-Mitschang et al [8]. Moreover, Excellent agreement between the SDFMM and the MoM is presented in Fig. 3, where the bistatic scattering cross section σ of the buried spheroid under an individual rough surface realization is shown. To be able to calculate the surface currents using the MOM, the ground dimensions are assumed (in this example) to be $2.96\lambda_0 \times 2.96\lambda_0$. Results in Fig. 3 are obtained at incident angle $\vartheta^i = 0^\circ$ and for the VV-polarization. For these results, the total CPU time (filling the impedance matrix, convergence f iterative solver, and calculating near fields and radar cross sections) is 59 minutes for the MoM with 511MB required computer memory, while they are only 31 minutes and 140MB, respectively, for the SDFMM.

Figure 2. Validation of the SDFMM code (target only) for bistatic scattering cross section σ_0 of penetrable sphere ($\epsilon_r = 1.75 - i0.3$, and $a = 0.2\lambda_0$). Comparison between current results and both Mie and MoM solutions as published in [8].

Figure 3. Validation of the SDFMM with the MoM for bistatic scattering cross section σ_0 of penetrable oblate spheroid ($\epsilon_r = 2.9 - i0.072$, $a = 0.3\lambda_0$, $b = 0.15\lambda_0$) buried at depth $d = 0.3\lambda_0$ under rough ground of dielectric constant $\epsilon_r = 2.5 - i0.18$, rms height $\sigma = 0.04\lambda_0$ and correlation length $l_c = 0.5\lambda_0$ (one realization) at incident angle $\vartheta^i = 0^\circ$ for VV - polarization.

The dimensions of the ground are assumed $8\lambda_0 \times 8\lambda_0$ with roughness parameters as rms height $\sigma = 0.04\lambda_0$ and correlation length $l_c = 0.5\lambda_0$. The ground is a typical Bosnian soil with 3.8% moisture and dielectric constant $\epsilon_r = 2.5 - i0.18$ at 1GHz [6]. The dielectric constant of the *TNT* mine is $\epsilon_r = 2.9 - i0.072$ which is modeled as an oblate spheroid with $a=2b=0.3\lambda_0$ (top view is a circle). The *TNT* mine is buried at $d = 0.3\lambda_0$ from its center to the mean plane of the rough ground. The incident Gaussian beam is pointing normally at the center of the ground. The difference in the near electric fields scattered from the rough ground without buried target and those scattered from the same ground but with buried target, are the scattered fields due just to the buried target. We repeated this subtraction process for each of the 65 rough surface realizations, and took the statistical average of the all scattered fields using Eq. 1. Thus the average signature of the target is obtained and plotted in Fig. 4a. The results show that the *TNT* mine has signature almost equal to 5% of the total scattered fields [5]. Similar results to Fig. 4a are obtained at different locations of the buried target as $x = y = 5.0\lambda_0$ and shown in Fig. 4b and $x = 6.5\lambda_0, y = 4.0\lambda_0$ as shown in Fig. 4c. These results show the degradation of object signature as function of its closeness to the center of the incident Gaussian beam. Using Eq. 2, the standard deviation (*STD*) of the 65 scattered electric fields due just to the target is calculated and plotted in Fig. 5. The results show that the *STD* of the target signal is almost 30% of the target signature shown in Fig. 4a.

Figure 4a. Average near electric field scattered due to only buried object obtained by subtracting scattered from rough ground without buried target from those scattered from rough ground with buried target, then take the statistical average. Incident angle $\vartheta^i = 0^\circ$ for horizontal polarization. The target is buried at $x = y = 4.0\lambda_0, z = -0.3\lambda_0$.

Figure 4b. Average near electric field scattered due just to the object for the same data in Fig. 4a except for the target is buried at $x = y = 5.0\lambda_0, z = -0.3\lambda_0$.

Figure 4c. Average near electric field scattered due just to the buried object for the same data as in Fig. 4a except for the target is buried at $x = 6.5\lambda_0, y = 4.0\lambda_0, z = -0.3\lambda_0$.

Figure 5. Standard deviation (*STD*) of near electric fields scattered due to just buried spheroid for the same data in Fig. 4a.

3. Conclusions

In this work, the statistics of the scattered fields due just to the buried *TNT* mine are obtained using the modified fast code SDFMM. Monte Carlo simulations are conducted to obtain the scattered fields from the two-dimensional random rough ground once with the target and once without the target. The average and standard deviation of the scattered fields due to just the target are calculated by subtraction. The results showed the significant distorting effect of the rough ground. Moreover, this study showed the degradation of the *TNT* mine signal if it is located away from incident beam.

In anti-personnel mine detection applications, explosive objects buried under ground with rough soil surface could be surrounded by different clutter objects such as rocks, roots, sticks, metallic nails, vegetation, etc. Target discrimination between the AP mine and any sort of object clutter is necessary to minimize false alarms.

In this work, we present the analysis of the electromagnetic wave scattered from two objects buried under a 2-D random rough surface. These two buried objects could both be perfect electric conductors (PEC), one plastic object and one PEC, or two plastic objects. The random height variation of the rough ground is assumed to have Gaussian probability density function and the surface autocorrelation function is assumed Gaussian as well. A carefully tapered Gaussian beam is assumed for incident waves.

The integral equation-based fast algorithm, the Steepest Descent Fast Multipole Method (SDFMM), will be implemented in this work to calculate the electric and magnetic surface currents on the soil/ground interface and the multiple objects. The great advantage of the SDFMM lies in its $O(N)$ computational complexity versus the $O(N^2)$ for the Method of Moment (MOM) to solve N linear system of equations using an iterative solver. The SDFMM was originally developed at UIUC.

In our previous work, we used the SDFMM to analyze the near electric field scattered from single plastic object buried under the rough ground. The rough ground surface was the only source of clutter in the surrounding environment. Here, we are adding another source of clutter that is the proximity of an un-explosive object to the AP mine. The effect of the proximity and orientation of clutter object on target signature will be investigated here. Our objective is to understand the physics behind the mechanism of scattering from these two buried objects and hence to be able to discriminate between the explosive target and the clutter object.

Electromagnetics Computations Using the MPI Parallel Implementation of the Steepest Descent Fast Multipole Method (SDFMM).

Abstract

The computational solution of large-scale linear systems of equations necessitates the use of fast algorithms, but is also greatly enhanced by employing parallelization techniques. The objective of this work is to demonstrate the speedup achieved by the MPI-based parallel implementation of the Steepest Descent Fast Multipole Method (SDFMM). Although this algorithm has already been optimized to take advantage of the structure of the physics of scattering problems, there is still the opportunity to speed up the calculation by dividing component tasks into pieces and using multiple processors to solve them in parallel. The SDFMM has three bottlenecks ordered as (1) filling the sparse impedance matrix associated with the near field moment method interactions, (2) the matrix vector multiplications associated with this sparse matrix (3) the far field interactions associated with the fast multipole method. The parallel implementation task is accomplished basically using a thirty-one node Intel Pentium Beowulf cluster and is also validated on a 4-processor Alpha workstation. The Beowulf cluster consists of thirty-one nodes of 350MHz Intel Pentium IIs with 256 MB of RAM and one node of a 4x450MHz Intel Pentium II Xeon shared memory processor with 2GB of RAM with all nodes

connected to a 100 BaseTX Ethernet network. The Alpha workstation has a maximum of four 667MHz processors. The parallelized computer code is tested for different cases of the anti-personnel landmine detection application. Our numerical results show linear speedup in filling the sparse impedance matrix that tremendously reduced the overall code's runtime. Using the 32-processors on the Beowulf cluster lead to achieve a 7.2 overall speedup and significant reduction in the runtime is gained using the 4-processors on the Alpha workstation.

I. Introduction

The SDFMM is an integral equation-based fast algorithm that is a hybridization of (1) the Method of Moment (MoM), (2) the Fast Multipole Method (FMM), (3) the Steepest Descent Integration rule (SDP) [1]-[3]. Recently the SDFMM computer code has been successfully modified to handle subsurface sensing applications, in particular, the scattering from a landmine modeled as a PEC and/or penetrable spheroid buried under a two dimensional randomly rough ground [4]-[5]. The SDFMM has computational complexity for the CPU time and for the memory requirement equal to only $O(N)$ per iteration versus $O(N^2)$ for the MoM, where N is the total number of the unknowns [1]-[3]. The significant reduced complexity of the SDFMM over several other computational electromagnetics techniques has helped in achieving a fast and successful running for the Monte Carlo simulations [5]. However, the Monte Carlo sample needs in some cases to be greatly increased, e.g. when the ground random roughness increases the size of the Monte Carlo sample needs to be increased to achieve a converging solution. This could dramatically increase the required run time, especially when the dielectric constant of the ground is large and/or the penetrable buried object is electrically large. This necessitates a parallel

implementation of the SDFMM code to further reduce the overall runtime of large-scale 3-D scattering problems.

In this work, we used the MPI library for the parallel implementation of the SDFMM code [6]. The advantage of using the Beowulf cluster is that the system can be completely dedicated for the parallelization task, which is demonstrated in this work by executing small-scale cases due to memory limitations. Our emphasis is to demonstrate the overall speedup that can be achieved using the thirty-two processors [7]. Porting the parallelized code to the national supercomputers, where hundreds of processors and adequate RAM are available, will potentially facilitate the computations of large-scale problems [7]-[9].

The parallelization technique will be described in Section II, the numerical results will be shown in Section III and concluding remarks will be given in Section IV.

II. Parallelization Methodology

The SDFMM makes use of the equivalence theorem to calculate the electric and magnetic fields inside and outside a 3-D penetrable object buried under the rough surface interface [4]-[5]. The 3-D arbitrary object is modeled by scatterer R_3 that is immersed in scatterer R_2 which represents the rough ground which is immersed in the free space region represented by R_1 . The three regions, R_1 , R_2 and R_3 have permittivity and permeability given by ϵ_1 and μ_1 , ϵ_2 and μ_2 , and ϵ_3 and μ_3 , respectively, representing free space, soil medium and penetrable buried object. There are two final sets of unknown equivalent electric and magnetic surface currents in the following formulations. They are \bar{J}_1, \bar{M}_1 on the exterior of the rough ground interface between R_1 and R_2 , and \bar{J}_3, \bar{M}_3 on the exterior of the buried object interface between R_2 and

R_3 . Upon applying the boundary conditions, continuity of tangential components of the electric and magnetic fields on these interfaces, new integral equation formulations are obtained as [4]-[5]:

$$\bar{E}^{inc}(\bar{r})\Big|_{\text{tang.}} = \left[(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 - L_3\bar{J}_3 + K_3\bar{M}_3 \right]_{\text{tang.}} \quad (1a)$$

$$\bar{H}^{inc}(\bar{r})\Big|_{\text{tang.}} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 - K_3\bar{J}_3 - \frac{L_3}{\eta_2^2} \bar{M}_3 \right]_{\text{tang.}} \quad (1b)$$

$$0 = \left[-L_2\bar{J}_1 + K_2\bar{M}_1 + (L_3 + L_4)\bar{J}_3 - (K_3 + K_4)\bar{M}_3 \right]_{\text{tang.}} \quad (1c)$$

$$0 = \left[-K_2\bar{J}_1 - \frac{L_2\bar{M}_1}{\eta_2^2} + (K_3 + K_4)\bar{J}_3 + \left(\frac{L_3}{\eta_2^2} + \frac{L_4}{\eta_3^2} \right) \bar{M}_3 \right]_{\text{tang.}} \quad (1d)$$

In which the integro-differential operators L_i and K_i , $i=1, 2, 3$ and 4 , are given in detailed in [5]. In Eqs. 1a-d, the unknown surface electric and magnetic currents are \bar{J}_1 , \bar{M}_1 , \bar{J}_3 , and \bar{M}_3 , while the tangential component of the incident electric and magnetic fields on the rough surface are given by $\bar{E}^{inc}(\bar{r})\Big|_{\text{tang.}}$ and $\bar{H}^{inc}(\bar{r})\Big|_{\text{tang.}}$, respectively. The intrinsic impedance in each region is $\eta_i = \sqrt{\mu_i / \epsilon_i}$, $i=1, 2$, and 3 , where the dielectric permittivity and permeability in each region are ϵ_i and μ_i , respectively. The equivalent electric and magnetic currents are approximated using the RWG vector basis functions [10]-[11]. Upon applying Galerkin's method for testing and substituting the RWG surface current approximations in 1a-d, the original integral equations are transformed into a set of linear system of equations given by [4]-[5]:

$$\bar{\bar{Z}} \bar{I} = \bar{V} \quad (2a)$$

The impedance matrix $\bar{\bar{Z}}$ has order of $2(N+P) \times 2(N+P)$. The vector \bar{V} is a matrix of order $2(N+P) \times 1$ and composed of a submatrix of the tested tangential incident electric field \bar{E}^{inc} of order $N \times 1$ and a submatrix of the tested normalized magnetic field $\eta_1 \bar{H}^{inc}$ of order $N \times 1$, and a null submatrix of order $2P \times 1$. The quantities N and P are the number of basis functions (total number of edges of the triangular patches) on the surfaces of the rough ground and the buried object, respectively. If the MoM is used to solve Eq. (2a), it requires computing and storing all elements of the matrix $\bar{\bar{Z}}$ and then multiplying them by the vector \bar{I} , which is considered a very expensive computational process that will prohibit solving (2a) for large-scale problems. However, upon using the SDFMM [1]-[5], the matrix $\bar{\bar{Z}}$ becomes sparse and the system of equations in (2a) can be written as:

$$\bar{\bar{Z}}' \bar{I} + \bar{\bar{Z}}'' \bar{I} = \bar{V} \quad (2b)$$

where the matrix $\bar{\bar{Z}}'$ is a sparse matrix whose non-zero elements need to be calculated and stored using the conventional MoM and then multiplying them by the vector \bar{I} (near field interactions) while the matrix-vector multiply $\bar{\bar{Z}}'' \bar{I}$ is computed in one step without calculating or storing any elements of the matrix $\bar{\bar{Z}}''$. This is achieved by using the FMM hybridized with the SDP integration rule. This implies that there are three bottlenecks in the SDFMM code that can significantly enhance its performance by parallelization: (i) the subroutines that calculates the elements of the sparse matrix $\bar{\bar{Z}}'$; (ii) the subroutine that executes the matrix vector multiplication $\bar{\bar{Z}}' \bar{I}$ in each iteration of the solver; (iii) the subroutine that execute the fast multipole method for $\bar{\bar{Z}}'' \bar{I}$ (far field fast multipole interactions).

The computer code has been parallelized by exploiting the underlying available data parallelism. The key data structure in subroutine (i) is the sparse matrix $\bar{\bar{Z}}'$, which is stored as blocks of nonzero elements. These blocks are distributed among all processors, and no additional communication is needed. When this routine is parallelized we achieved near-linear speedups on 32 processors. In the matrix-vector multiplication $\bar{\bar{Z}}'\bar{I}$, the computation is parallelized by distributing \bar{I} to all processors in each iteration. The resulting vector components produced by the multiplication are then distributed to all processors. For bottleneck (iii), there are two involved subroutines to compute the far field interactions and they consist of a series of loops with complex interdependences. Each loop is separately parallelized, with collective communication used to distribute the results to all processors after executing each subroutine. In addition these two subroutines are executed in parallel, followed by another distribution of the results to all processors. Load balance between these two subroutines is achieved using a detailed performance model based on the serial execution time of each routine, the time required for collective communication operations, and the amount of communication overhead needed. Processors are assigned to these two subroutines such that the predicted maximum runtime for the two of them is minimized. The structure of the parallelized SDFMM application is shown in Fig. 1.

II. Numerical Results

We evaluated the parallel implementation of the SDFMM computer code on a 32-node Intel Pentium-based Beowulf cluster. Thirty one nodes of the Beowulf cluster are 350MHz Intel Pentium IIs with 256 MB of RAM in addition to one node of a 4x450MHz Intel Pentium II Xeon shared memory processor with 2GB of RAM. The nodes are connected to a 100 BaseTX

Ethernet network and they use the SuSE 6.1 operating system with Linux kernel 2.2.13, and the MPICH 1.2.1 implementation of the MPI library. Moreover, we tested the parallelized code on a 4-node shared memory Compaq Alpha-based workstation (667Mhz Alpha 21264) of 16GB total RAM. The processor uses the UNIX OSF/1 V5.1 operating system with the MPICH 1.1.2 MPI library.

Our benchmark includes three small-scale cases executed on the 256MB Intel cluster, and in addition one moderate-scale case that is executed on the Alpha workstation. To evaluate the speedup achieved by the parallel code, we considered a range of values for the ground roughness and/or for the buried object. All results obtained by executing the parallel version of the code are validated with those computed by the serial version of the code [4]-[5]. In all computations a 0.1% tolerance is assumed for the TFQMR iterative solver. The scattering problem configurations used in [5] are employed here, but for only one rough surface realization. The rough ground is characterized by Gaussian statistics with zero mean for the height, thus the roughness parameters can be described by the rms height (σ) and the correlation length (l_c). In all cases, the relative dielectric constant of the ground soil and the penetrable buried object (anti-personnel mine) are $\epsilon_r = 2.5 - j0.18$ and $\epsilon_r = 2.9 - j0.0092$, respectively. A Gaussian beam with horizontal polarization is employed for the incident waves at normal incidence for Cases 1-3 and at 10° from normal direction for Case 4 [5].

In the small-scale Cases 1-3, the dimensions of the modeled ground are assumed to be $3\lambda_0 \times 3\lambda_0$ leading to almost 8,800 of total number of surface current unknowns, while these dimensions are increased to be $8\lambda_0 \times 8\lambda_0$ for the moderate-scale Case 4 leading to 60,320 unknowns, where λ_0 is the free space wavelength. In Case 1, the scattered electric fields from a rough ground alone (no buried target) with $\sigma = 0.3\lambda_0$ and $l_c = 0.5\lambda_0$ are calculated at height of

$1.2\lambda_0$ above the ground. In Case 2, the scattered electric fields from a rough ground with a buried penetrable sphere are calculated at height of $0.5\lambda_0$ above the ground. The ground roughness are assumed to be $\sigma = 0.1\lambda_0$ and $l_c = 0.5\lambda_0$ and the sphere has radius of $a = 0.16\lambda_0$ with burial depth equal to $z = -0.32\lambda_0$ measured from its center to the mean plane of the ground. The sphere in Case 2 is replaced by a spheroid of dimensions $a = 0.3\lambda_0$ and $b = 0.15\lambda_0$ in Case 3 that is buried at $z = -0.3\lambda_0$ with ground roughness equal to $\sigma = 0.04\lambda_0$ and $l_c = 0.5\lambda_0$.

Both the overall speedup and the initial speedup (filling matrix $\bar{\bar{Z}}'$) are plotted versus the number of processors for Cases 1, 2 and 3 in Figs. 2a, 2b and 2c, respectively. The speedup is defined as the ratio of the serial runtime to the parallel runtime. The results in these figures show the significant speedup in the initial time (set up) that is consumed to fill the sparse matrix $\bar{\bar{Z}}'$ as explained in Section II. This initial speedup dramatically affects the overall speedup of the code as shown in these figures. In addition, the results show that almost the same overall speedup can be achieved by employing only twelve instead of thirty-two processors.

The efficiency for a given number of processors is defined as the ratio of the speedup to the number of processors. In each case, the peak speedup is achieved when running on 32 processors, where for case 1, the peak speedup is 7.1 as shown in Fig. 2a, with a reduction in runtime from 99 minutes on one processor to 14 minutes on 32 processors. For Case 2, the peak speedup is 6.2 as shown in Fig. 2b, with a reduction in runtime from 90 minutes to 14 minutes while for Case 3, the peak speedup is 7.2 as shown in Fig. 2c, with a reduction in runtime from 88 minutes to 12 minutes. Over these three cases, the average speedup on 32 processors is 6.8, giving an efficiency of 0.21. Based on the serial runtimes, 88% of the code is executed in parallel. Therefore by Amdahl's Law [12], the peak speedup achievable is 8.3. We conclude that

communication overhead and load imbalance among the processors accounts for the reduction in speedup from 8.3 to 6.8. An interesting comparison between the speedup achieved in each one of the bottlenecks (i)-(iii) mentioned in Section II, is shown in Fig. 3. These results show that overall speedup is almost the same as the speedup achieved in the matrix-vector multiplication $\bar{\bar{Z}}\bar{I}$ that is the bottleneck (ii).

In the second set of experiments, we solved the moderate-scale problem of Case 4 (60,320 unknowns) on the Alpha SMP using all four available processors. The penetrable spheroid of dimensions $a = 0.3\lambda_0$ and $b = 0.15\lambda_0$ is buried at $z = -0.3\lambda_0$ under the $8\lambda_0 \times 8\lambda_0$ rough ground with $\sigma = 0.04\lambda_0$ and $l_c = 0.5\lambda_0$. The magnitude of the total scattered electric field from the ground with the buried target is shown in Fig. 4a. However, the magnitude of the scattered electric fields for just the buried spheroid is computed by subtracting the return from the rough ground using complex vector representation from the total return from the ground with the buried target [4]-[5]. The output is shown in Fig. 4b. The results of Fig. 4a and 4b clearly demonstrate that the signature of the buried plastic landmine is relatively small compared with the return from the ground which is considered a major source of clutter in landmine detection application. Moreover, the distortion observed in Fig. 4b is due to the roughness of the ground which is modeled here as only one random rough surface realization, however the Monte Carlo simulations case was presented in [5]. The serial version took 96 minutes to run this case while the parallel version took 37 minutes, giving a speedup of 2.5 and an efficiency of 0.63. The predicted peak speedup on the four processors is 2.9. This implies that executing the parallel code on the 4-Alpha 667MHz processor gives a remarkable reduced absolute runtime for this moderate-scale case. This achievement can be exploited to execute large-scale scattering problem as mentioned in Section II. For the memory requirements, the serial version of the code

requires 950MB of RAM while the parallel version requires 1154MB of RAM distributed over the four processors as 288, 290, 289 and 287MB, respectively. Table I summarizes the parameters and output results for all cases presented in this section.

Table I

Case #	# of Unknowns	σ	Object	System	# of Processors	Serial/Par. Time (min.)	Speedup (overall)
1	8,800	$0.3\lambda_o$	None	Cluster	32	99/14	7.1
2	8,800	$0.1\lambda_o$	Sphere	Cluster	32	90/14	6.2
3	8,800	$0.04\lambda_o$	Spheroid	Cluster	32	88/12	7.2
4	60,320	$0.04\lambda_o$	Spheroid	Alpha Server	4	96/37	2.5

The results described in this section demonstrate that by implementing the fine grained parallelism, we have achieved significant speedups when using a single rough surface realization (one run of the code). However, when the number of rough surface realizations is much larger than the number of available processors, larger speedups are possible. In this case we assign a group of these realizations (runs of the code) to be executed in parallel on each processor. Since the computations are independent, this coarse grained parallelism gives a perfect speedup that is only limited by the number of available processors with the advantage that no communication is required. This situation occurs when we need to run Monte Carlo simulations [5]. In other subsurface scattering configurations, we may need to obtain multiple views of a target buried under the same rough surface realization [4], which requires running the code only few times. A combination of the fine-grained parallelism and coarse-grained parallelism can make efficient use of all available processors. Reasonable speedup can be achieved in this case where the number of needed runs is comparable to, or smaller than, the number of the available processors.

IV. Conclusions

Remarkable speedup has been achieved as the SDFMM is parallelized using the MPI library. The linear speedup obtained for the bottleneck associated with filling the impedance sparse matrix indicates a significant accomplishment as it dramatically affects the overall speed of the computer code. Reasonable speedups are obtained for the second and third bottlenecks associated with the matrix vector multiplication and the far field approximations, respectively. However, both speedups saturate upon using a number of processors less than the total number of nodes available on the system. This mechanism causes the overall runtime of the code to be larger than what we anticipated. Thus more parallelization effort is needed especially for the second bottleneck (matrix vector multiplication for the sparse matrix) in order to achieve as much linear overall speedup as possible.

Abstract:

The Steepest Descent Fast Multipole Method (SDFMM) is used to analyze the distorting effect of random rough ground surfaces on scattered and transmitted electromagnetic waves. Two well-measured loamy soils: Bosnian and Puerto Rican clay loam are investigated, each with a variety of surface roughness. This study is important in understanding the effects of different soil properties and is meant to be an *a priori* phase of investigating scattering from buried targets under the rough ground. In this work, we investigated the scattering from rough soil ground without buried objects. The SDFMM is an integral equation-based fast algorithm that is well suited for two-dimensional penetrable rough surfaces (3-D scattering) in the frequency domain. The scattered and transmitted near electric field of an incident Gaussian beam are calculated at different locations above and below the mean plane of the dielectric rough interface. The

receiver locations above are chosen to simulate GPR measurement protocols. The obtained numerical results show that the scattered field undergoes more distortion than the transmitted field from both soil types. Moreover, the transmitted fields into the higher dielectric constant Puerto Rican soil experience more distortion than those transmitted into Bosnian soil.

Key words: Rough surface scattering, GPR, EM modeling, fast algorithms.

I. INTRODUCTION

When electromagnetic waves are used to sense buried objects, the effect of the random rough air/ground interface on both the transmitted and scattered fields is great, and must be carefully considered. In many cases, the scattering from the air/ground interface is larger than the scattering of a buried target especially when the ground surface roughness is comparable to the height and the burial depth of the target. Accurate modeling of the clutter is necessary to enable signal-processing algorithms to perform optimally in detecting buried targets. In this work, we investigate the clutter of different types of soil, which is scattering from rough surface without any buried targets.

The rough surface causes two types of distorting effects on a probing plane wave: a defocused scattered wave reflected back into the air, and a distorted transmitted wave that would continue until it encounters a target. Uncertainty is generated in both waves, and it is important to understand the relative amounts of distortion between the two, as well as its dependence on soil type. While there has been much published work on far field rough surface scattering [1]-[8], the near field effects— which are essential in inverse scattering and object sensing applications—

have not been well studied. However, there is published work for modeling near field from targets buried under planar surface [9]. As an effort to study the scattered fields in the near zone, we assumed that the incident waves are still far fields while point receivers are located in the near zone above and below the rough ground. No interactions between scattered fields and the transmitting antenna are accounted for in this work.

The surface scattering depends on the frequency dependent complex dielectric constant of the soil, which in turn depends on its composition, moisture and density, and also on the roughness of the surface. As moisture increases, so does the dielectric constant. And with a larger dielectric constant, the wavelength in soil decreases. For a given illuminated portion of ground, wetter soil will require finer computational discretization, and greater computational expense. However, using special-purpose numerical methods, the fast computation of wave interaction with a rough surface is feasible. We study two types of experimentally measured soil: Bosnian loam from the Alicia test site [10], and Puerto Rican clay loam [11].

The rough surface is characterized with Gaussian statistics in terms of random heights and auto-correlation function [12]. The roughness parameters (root mean square height and correlation length) are chosen to be in the moderate roughness range, with root mean square height ranging from 0.1 to 0.2 free space wavelengths and the correlation length kept constant at one free space wavelength.

In this work, a specialized fast algorithm is necessary, since multiple calculations of this realistic, but computationally intensive, model are needed for many different realizations of surface

roughness. There for we used the SDFMM, which is a hybridization of the Method of Moments (MOM), the Steepest Descent Path (SDP) method, and the Fast Multipole Method (FMM) [13], [14], to calculate the unknown surface current coefficients. The details of the SDFMM can be found in [15]-[18].

II. FORMULATION

In this work, the well-known PMCHW (Poggio, Miller, Chang, Harrington, and Wu) integral equations are implemented to calculate the electric and magnetic surface currents [16], [19]. For convenience, the integral equation are summarized here as:

$$\bar{E}^{inc}(\bar{r})\Big|_{tan.} = \left[(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 \right]_{tan.} \quad (1)$$

and

$$\bar{H}^{inc}(\bar{r})\Big|_{tan.} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 \right]_{tan.} \quad (2)$$

in which $\bar{E}^{inc}(\bar{r})$ and $\bar{H}^{inc}(\bar{r})$ are the incident electric and magnetic fields on the interface between air and soil as shown in Figure (1). The subscript *tan* means the tangential component.

The differentio-integral operators L_1, L_2, K_1 and K_2 are defined as [19]:

$$L_{1,2}\bar{X} = \int_S \left\{ i\omega\mu_{1,2}\Phi_{1,2}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{1,2}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{1,2} \right\} ds' \quad (3a)$$

$$K_{1,2}\bar{X} = \int_S \bar{X}(\bar{r}') \times \nabla\Phi_{1,2} ds' \quad (3b)$$

where, the vector \bar{X} represents the surface electric current \bar{J} or the surface magnetic current \bar{M} on the interface S . The dielectric permittivity and permeability in each region are ϵ_i and μ_i , $i=1$ and 2. The 3-D scalar Green's function in $\Phi_i(\bar{r})$ is given by :

$$\Phi_i(\bar{r} - \bar{r}') = \frac{\exp(-ik_i|\bar{r} - \bar{r}'|)}{4\pi|\bar{r} - \bar{r}'|} \quad (3c)$$

in which \bar{r} is the field point, \bar{r}' is the source point, $k_i = \omega\sqrt{\epsilon_i\mu_i}$ is the wave number in each region, $i=1$ and 2 . The equivalent electric and magnetic currents \bar{J} and \bar{M} on S , are approximated using the RWG vector basis functions $\bar{j}(\bar{r})$ [19], [20] as follows

$$\bar{J}(\bar{r}) = \sum_{n=1}^N I_{1n} \bar{j}_n(\bar{r}), \quad \bar{r} \in S \quad (4a)$$

$$\bar{M}(\bar{r}) = \eta_1 \sum_{n=1}^N I_{2n} \bar{j}_n(\bar{r}), \quad \bar{r} \in S \quad (4b)$$

where η_1 is the intrinsic impedance of the free space. Upon substituting Eq. 3-4 in Eqs. (1) and (2) and testing with the same basis functions, we get the $2N \times 2N$ system of equations as

$$\bar{\bar{Z}}\bar{I} = \bar{V} \quad (5)$$

in which \bar{V} represents the tangential component of the electric and magnetic fields, \bar{I} represents the unknown coefficients, and $\bar{\bar{Z}}$ is the impedance matrix [19]. Solving Eq.(5) using the method of moments is extremely expensive (computer memory and CPU time) when the size of the scatterer (the rough interface, in this case) is much larger than the free space wavelength. In reality, the size of the ground is infinite but for computational consideration the rough ground is assumed to be adequately larger than the footprint of the incident Gaussian beam [21]. As the number of unknown coefficients is very large, special computational procedures must be used such as the SDFMM, which is discussed in [15]-[18] and recently was implemented in [22].

III. NUMERICAL RESULTS

We consider the scatterer S to be a penetrable random rough surface with dimensions equal to $L \times L$, where $L = 8\lambda_0$, and λ_0 is the free space wavelength. Exciting the surface with a carefully tapered incident Gaussian beam minimizes the edge effect of the surface S on the surface currents [21]. Thus, infinitely large rough surfaces are sampled over a manageable region. The random rough surface is characterized with Gaussian statistics for the random heights and for the autocorrelation function, and is generated using the computer random number generator following the technique in [12]. Sixty Monte Carlo rough surface simulations were calculated for each pair of Gaussian parameters: root mean square height σ and correlation length l_c . For cases considered here, the electric field is assumed to be x-directed, and normally incident ($\theta^i = 0$) on the nominal ground surface.

Similar to the work in [16], which implemented the SDFMM to calculate the radar cross section of a penetrable random rough surface, we also are using the SDFMM but to calculate the near electromagnetic fields scattered above and transmitted into the ground.

Point receivers are located in the near zone at one wavelength above and below the mean ground with resolution equal to $x = y = 0.1\lambda_0$. The electric field is calculated using the nearfield formulas in [23]. The SDFMM is compared with the sparse matrix canonical grid (SMCG) method [1] and excellent agreement is observed as shown in Fig. 2. The incident angle is $\theta^i = 20^\circ$, soil relative dielectric constant is $\epsilon_r = 2.0 - i0.2$, and surface roughness parameters are rms height $\sigma = 0.02\lambda_0$ and correlation length $l_c = 0.5\lambda_0$. The comparison in Fig. 2 shows the normalized radar cross section (RCS) for the HH-polarization case with horizontal axis to be the scatter angle θ (elevation angle in degrees) measured from the z -axis.

In this work, two types of soils have been studied: Bosnian soil with density 1.4g/cm^3 and 3.8% moisture level with complex dielectric constant $\epsilon_r = 3 - i0.18$ at 1 Ghz [10], and Puerto Rican clay loam with density 1.2 g/cm^3 and 10% moisture with dielectric constant $\epsilon_r = 5.4 - i0.04$ at frequency $f = 960\text{ Mhz}$ [11]. Three values of the rough ground rms height are assumed: $\sigma = 0.1\lambda_0$, $0.12\lambda_0$, and $0.17\lambda_0$ along with constant correlation length $l_c = 1\lambda_0$.

In Figs. 3a-c, the mean scattered fields in air from Bosnian soil with different rms random heights are shown, while Figs. 3d-f shows the transmitted fields. Note that for a perfectly flat ground surface, $\sigma = 0$; the contours would be perfect circles. In fact, with enough Monte Carlo runs, the mean scattered and transmitted field would be expected to be circularly symmetric for normal incidence. However, these mean fields show significant asymmetry and distortion, indicating that the random rough surface causes so much variation in the scattered fields that 60 runs is insufficient for convergence. As the rms height of the rough surface increases, the distortion in both the mean scattered and transmitted field increases as well. The asymmetry of the mean scattered and transmitted wave patterns give a qualitative sense of the distorting effects of the rough surface. Moreover, the results show that the waves transmitted into the ground, Figs. 3d-f, are less distorted than the scattered fields above the ground. This could be explained by noting that for rays incident on locally tilted surface patches (the sides of small hills and valleys), the reflected rays are bent further away from the nominal surface normal than the transmitted rays. As the surface roughness increases, the slopes of the surface patches increase, and the reflected rays diverge more. In Figs. 4a-c and 4d-f, the scattered and transmitted fields from Puerto Rican soil with the same three rms random heights are shown. Comparing results of Fig. 3 and Fig. 4, the magnitude of the scattered fields from the Puerto Rican soil is observed to

be larger--and the transmitted fields smaller--than that of the Bosnian soil. This is consistent with the fact that the dielectric constant for Puerto Rican soil is almost double that of Bosnian soil. Greater distortion in the transmitted fields in the Puerto Rican soil is observed as compared with the Bosnian soil case (Figs. 4d-f versus Figs. 3d-f). This results from the larger electrical distance in the former medium from the rough surface scattering centers to the observation plane one wavelength in air below the ground. The destructive interference of the transmitted Gaussian beam is enhanced when the phase differences from various parts of the surface proportionally increase.

Although the conductivity in soil plays an important role in subsurface sensing, it does not appear to have a dominant effect in the distortion of the transmitted Gaussian beam. A test of 60 Monte Carlo SDFMM runs of a fictitious soil medium with the real dielectric constant of Bosnian soil, but with the loss of the Puerto Rican clay loam indicates that the transmitted field has about the same distortion as for the actual Bosnian soil.

The total CPU time needed for filling the impedance matrix, for the iterative solution using the transpose free quasi-minimal residual solver (TFQMR) [24], and for calculating scattered and transmitted near fields is plotted versus the rough surface rms height and shown in Fig. 5. The discretization rate of the surface current, number of electric and magnetic surface current unknowns, and the required computer memory to run the SDFMM code are given in Table 1. As expected, running the SDFMM code for the Puerto Rican soil required more CPU time and computer memory due to its larger relative dielectric constant requiring a finer discretization.

The NCSA SGI/CRAY Origin 2000 machines are used for the Puerto Rican case due its larger memory requirement, but the Compaq GS140 EV6 machine at Northeastern University is used for the Bosnian case, which reflects the results shown in Fig. 5.

III. CONCLUSIONS

The SDFMM fast algorithm is used to calculate the nearfield scattered from and transmitted into two types of rough ground soils. Bosnian and Puerto Rican soils were chosen for this study as *a priori* phase of our investigation of scattering from buried mines under the same types of soils [22]. The results show that the distortion in both the scattered and the transmitted fields increases as the ground roughness increases. We observed that the scattered fields experience more distortion than the transmitted ones. This suggests a future research to investigate how will the transmitted fields be changing with the increase of the incident angle. This result indicates that although rough surfaces randomly distort both the scattered and transmitted waves, the distortion is greater for the former. Thus the uncertainty of the surface clutter signal is greater than that of the probing signal, suggesting the relative importance of careful characterization of the scattered waves.

ACKNOWLEDGEMENTS

The authors would like to thank Prof. W. Chew, Prof. E. Michielssen, and Dr. V. Jandhyala at UIUC for allowing us to use and modify the SDFMM computer code for the current application. This research was sponsored by the Army Research Office Demining MURI grant # DAA 0-55-97-0013 and in part by the Engineering Research Centers Program of the NSF under award number EEC-9986821. The computational work was partially supported by National

Computational Science Alliance under grant # pt1 and utilized the NCSA SGI/CRAY Origin 2000 and the allocation of time at the Northeastern University Advanced Scientific Computation Center (NU-ASCC).

Abstract

The multiple interaction model is hybridized with the robust Steepest Descent Fast Multipole Method (SDFMM) to compute the signature of non-shallow penetrable scatterers buried beneath 2-D random rough surfaces. The most attractive feature of the multiple interaction model with using the SDFMM is removing the quasi-planar structure constraint for analyzing non-quasi-planar scatterers. The results show that the buried object's signature is largely due to the first interaction mechanism; however, the contribution of each additional interaction is explicitly calculated, though they may become insignificant especially for lossy background soil.

I. INTRODUCTION

Modeling electromagnetic scattering from realistic three-dimensional subsurface sensing applications requires huge number of computational operations that necessitates the use of fast algorithms [1]-[6]. Recently, the SDFMM [3] has been adopted to analyze the scattering from penetrable shallow objects buried beneath two-dimensional random rough ground [7],[8]. The SDFMM has the great advantage of $O(K)$ computational complexity for both the CPU time and computer memory [3] compared with the $O(K^2)$ for the MoM, where K is the total number of electric and magnetic surface current unknowns. However, there is a barrier that limits using the SDFMM in some applications; the whole scatterer should have a quasi-planar structure with total height equal to a fraction of a free-space wavelength. On the other hand, there are several

potential applications that have non-quasi-planar geometries; e.g., the multi-layered rough ground where the burial depth of the underground layer is larger than the wavelength.

The multiple interaction approach was previously used in investigating electromagnetic scattering problems either analytically from rough surfaces only (no buried objects), e.g. [9] and [10], or computationally from rough surfaces with buried objects, e.g. [11], [12]-[14]. In [9] and [10], each scattering element on the rough surface was assumed to be a second source for all scattering elements either on the same surface leading to the double scattering mechanism [9], or on the underground rough-layer as presented in [10]. On the other hand, in [11] a PEC sphere was buried beneath the rough ground while in [12],[13] a penetrable object was buried under or located above the rough ground. In addition, the multiple interaction approach is used with the Multilevel Fast Multipole Algorithm (MLFMA) for multiple targets located above the half space is presented in [14]. In these models, the coupling between the rough ground and the object is expressed as interaction matrices.

The multiple interaction approach with using the SDFMM is presented in this work. The basic idea is to decompose the 3-D non-quasi-planar structure (e.g., the rough ground with a buried scatterer) into two quasi-planar scatterers as shown in Fig. 1 where the SDFMM can be used separately for each scatterer. However, the interactions between the ground and the buried scatterer are not expressed in matrices (or submatrices) but are calculated concurrently using pre-computed and pre-stored information that facilitated the numerical evaluating of the near-field expressions given in [15]. In general, using the multiple interaction approach (with and/or without the SDFMM) enables investigating the contribution of each individual interaction mechanism between the ground and the buried object. This will greatly help in understanding the physics involved in subsurface sensing applications. It is necessary to distinguish between the multiple interaction model upon using the SDFMM, presented in this work, and our previous

complete SDFMM model, presented in [7] and [8]. All the self and mutual interactions between the rough ground and the buried object were expressed as submatrices in the total impedance matrix of the whole scatterer in [7]-[8].

II. FORMULATION

The four integral equations describing the unknown equivalent electric and magnetic surface currents for the problem of a single object buried beneath two-dimensional rough ground were derived and discussed in [7], [8]. The surfaces of the ground and the buried object were discretized using the RWG triangular patches [16]; and the set of linear system of equations was obtained [7]-[8]:

$$\begin{pmatrix} \bar{Z}_{g.g} & \bar{Z}_{g.obj} \\ \bar{Z}_{obj.g} & \bar{Z}_{obj.obj} \end{pmatrix} \begin{pmatrix} \bar{I}_g \\ \bar{I}_{obj} \end{pmatrix} = \begin{pmatrix} \bar{V}_g \\ 0 \end{pmatrix} \quad (1)$$

where $\bar{Z}_{g.g}$ represents the interactions between elements only on the ground surface; $\bar{Z}_{g.obj}$ represents interactions between elements on the ground surface and elements on the object surface; $\bar{Z}_{obj.g}$ represents interactions between elements on the object surface and elements on the ground surface; and $\bar{Z}_{obj.obj}$ represents interactions between elements only on the object surface. As discussed in [7], the total impedance matrix \bar{Z} has order of $2(N+P) \times 2(N+P)$, where N is the number of vector basis functions on the ground and P is the number of vector basis functions on the buried object. The factor of two accounts for both the electric and magnetic surface currents. The vector \bar{V}_g represents the tested tangential incident electric and magnetic fields on the ground surface. The unknown coefficients \bar{I}_g and \bar{I}_{obj} were solved for in [7] and [8] by completely applying the SDFMM to (1) leading to converting the dense matrix \bar{Z} into a sparse one. Conversely, in this work, the multiple interaction approach will be used to

solve two separate linear systems of equations for the unknown current coefficients and then iteratively update the incident fields on both the ground and the buried object as

$$\bar{Z}_{g.g} \bar{I}_g^{(n)} = \bar{V}_g^{(n)} \quad (2a)$$

$$\bar{Z}_{obj.obj} \bar{I}_{obj}^{(n)} = \bar{V}_{obj}^{(n)} \quad (2b)$$

where $n = 1, 2, 3, \dots$ is the number of the interactions between the ground and the buried object as depicted in Fig. 2. The algorithm begins with solving (2a) for $\bar{I}_g^{(0)}$, updating $\bar{V}_{obj}^{(1)}$ in (2b) by numerically evaluating the near-field surface integrations given by Eqs. 107-111 in Chapter 6 [15], solving (2b) for $\bar{I}_{obj}^{(1)}$, updating $\bar{V}_g^{(1)}$ in (2a), and finally solving (2a) for $\bar{I}_g^{(1)}$. These steps represent one interaction mechanism (i.e., ground-object-ground) that should be repeated until convergence of surface current solutions is achieved. The final updated electric and magnetic surface currents on the ground will be $\bar{J}_g = \bar{J}_g^{(0)} + \bar{J}_g^{(1)} + \bar{J}_g^{(2)} + \dots + \bar{J}_g^{(n)}$ and $\bar{M}_g = \bar{M}_g^{(0)} + \bar{M}_g^{(1)} + \bar{M}_g^{(2)} + \dots + \bar{M}_g^{(n)}$, respectively, and on the object $\bar{J}_{obj} = \bar{J}_{obj}^{(1)} + \bar{J}_{obj}^{(2)} + \bar{J}_{obj}^{(3)} + \dots + \bar{J}_{obj}^{(n)}$ and $\bar{M}_{obj} = \bar{M}_{obj}^{(1)} + \bar{M}_{obj}^{(1)} + \bar{M}_{obj}^{(2)} + \dots + \bar{M}_{obj}^{(n)}$, respectively. In order to accelerate the computations, the SDFMM can be used separately in (2a) and in (2b) to convert each dense impedance matrix $\bar{Z}_{g.g}$ and $\bar{Z}_{obj.obj}$ into sparse one leading to the multiple interaction model with the SDFMM. However, the efficient use of the SDFMM is contingent on the geometry of each scatterer separately, i.e., both the rough ground and the buried object should be quasi-planar structures. In this case, one interaction mechanism between the ground and the buried scatterer requires solving (2a) two times, solving (2b) only once, and numerically evaluating the near field expressions in [15] once for the object's and once for the ground's incident fields. This implies that SDFMM is not used in the near-field interaction computations given in [15]. Thus if K_1 and K_2 are the number of the RWG triangular patches on the rough

ground and on the object, respectively, then evaluating the near-field expressions in [15] using patch-patch interactions requires $2K_1K_2$ operations [16]. Moreover, all the information needed to evaluate these surface integrations are pre-calculated and pre-stored during the computations of $\bar{Z}_{g, g}$ and $\bar{Z}_{obj, obj}$. Thus the overall number of operations for the multiple interaction model with the SDFMM is proportional to $2N + 2N + 2P + 4K_1K_2 = (4N + 2P + 4K_1K_2)$. The quantity $(4K_1K_2)$ can be approximated by $(16NP/9 \approx 2NP)$ [16]. However, it is crucial to indicate that these $(2NP)$ operations are conducted only once in each interaction mechanism and they are not conducted in every iteration of the iterative solver like the $(4N+2P)$ operations. The Transpose Free Quasi Minimal Residual (TFQMR) iterative solver is used in this work [17]. The memory requirements in the multiple interaction model with the SDFMM is $O(2N+2P)$. On the other hand, the computational complexity of the complete SDFMM is $O(2N+2P)$ [3],[7],[8], the conventional MoM is of $O((2N+2P)^2)$, and the multiple interaction model is of $O(4N^2 + 4P^2)$ for both the CPU time and computer memory. In the case where the buried scatterer has a non-quasi-planar structure but instead has a small electrical size, the multiple interaction model can still be used by solving (2a) using the SDFMM while solving (2b) using the MoM (i.e. the multiple interaction model with partial use of the SDFMM). This scenario will slightly increase the total computational operations. However, if the non-quasi-planar buried scatterer has a very large electrical size, then using the MoM to solve (2b) will lead to a significant increase in the computational operations. In addition, the coupling $(2NP)$ operations per interaction will increase as well which limits the use of the multiple interaction model for this case.

III. NUMERICAL RESULTS

Basically we are interested in subsurface sensing problems where calculating the surface currents on the rough ground dominates the overall computations. In all results presented in this

section, the incident wave is assumed a Gaussian beam tapered towards the edges of the ground [18] with horizontally polarized incident electric field (i.e., in the y -direction). The half-beam width is $L/5$ where the ground has dimensions $L \times L$.

A variety of geometries represented by seven examples are used in this section. For Examples 1-5, the geometries are described in Fig. 2a-f where the ground media is lossy with relative dielectric constant assumed as $\epsilon_{2r} = 2.5 - j0.18$. However, to investigate the case of a shallow scatterer buried in a lossless medium, Example 6 uses the geometry in Fig. 2c but for larger dimensions of the ground given by $4.08\lambda_0 \times 4.08\lambda_0$ with $\epsilon_{2r} = 2.5$ while the underground layer is assumed to have $\epsilon_{3r} = 6.7 - j0.2$ and is buried at $z = -0.1\lambda_0$. The same geometry is also used in Example 7, but with even larger dimensions of the ground given by $8\lambda_0 \times 8\lambda_0$, same lossless soil of $\epsilon_{2r} = 2.5$, and lossy underground layer of $\epsilon_{3r} = 6.7 - j1.0$ buried at $z = -0.1\lambda_0$. The accuracy of the near-field expressions in [15] deteriorates for burial depths smaller than $0.1\lambda_0$ since the source and observation points become very close to each other.

A qualitative comparison (not presented here) showed excellent agreement between the surface currents obtained using the multiple interaction model with those obtained using the conventional MoM. Moreover, the convergence of the surface current solutions in Examples 1-7, is quantitatively demonstrated by plotting the normalized change in the currents $\|C^{(n)}\|/\|C^{(0)}\|$ versus the number of interactions between the ground and the buried scatterer. This is shown in Fig. 3. The vector C has dimensions of $(2N+2P)$ and it contains all the electric and magnetic surface currents on both the air/ground interface and the buried scatterer. The results show that a significant change occurs in the currents after one interaction ($n = 1$); however, much less significant change in the currents is observed after two interactions ($n = 2$), as shown for Examples 6 and 7, where the maximum relative change in the currents is less than 5%. However,

insignificant changes are observed for all cases at the third or higher interaction. This indicates that the contributions from the higher interactions depend on the physical properties of the scatterer, and in some cases, larger changes in the currents may occur at the second interaction. In Fig. 4, the error in the norm of the surface currents obtained using the multiple interaction model $\|C\|_{\text{Model}}$ and those obtained using the conventional MoM ($\|C\|_{\text{MoM}}$) are plotted versus the number of interactions for Examples 1-4. The results clearly validate the multiple interaction model.

In Fig. 5a, the scattered electric fields received above the ground at $z = 0.5\lambda_0$ and due just to the buried sphere are plotted versus the x -direction for $y = 2.04\lambda_0$ using the data of Example 4 (Fig. 2e). Three solutions are obtained for this example (i) the conventional MoM for the whole scatterer, (ii) the multiple interaction model (MIM), and (iii) the multiple interaction model with the SDFMM (MIM with SDFMM). The observed slight differences are attributed to the difference in defining the scattered fields due to just the buried sphere in both the conventional MoM and the multiple interaction model. Using the conventional MoM, we calculated the total scattered electric fields twice; with and without the buried sphere, then the results are subtracted from each other with complex vectors [7],[8]. On the other hand, using the multiple interaction model we use the obtained surface currents on the ground due to only the presence of the sphere, i.e., $\bar{J}_g^{(1)} + \bar{J}_g^{(2)} + \bar{J}_g^{(3)}$ and $\bar{M}_g^{(1)} + \bar{M}_g^{(2)} + \bar{M}_g^{(3)}$, and incorporate them into the near field expressions in [15] to compute the scattered electric fields above the ground. Notice that the quantities $\bar{J}_g^{(0)}$ and $\bar{M}_g^{(0)}$, the surface currents on the ground without a buried object, are not used in the calculations of the object signature. In Fig. 5b, the scattered electric fields received above the ground at $z = 0.5\lambda_0$ are plotted versus the y -direction for $x = 2.04\lambda_0$ using the data of Example 5 (Fig. 2f). The scattered fields due to just the air/ground rough interface are calculated using only the

ground surface currents without the presence of the buried layer, i.e., $\bar{J}_g^{(0)}$ and $\bar{M}_g^{(0)}$, while the scattered fields due to just the underground rough layer are calculated using only the ground surface currents $\bar{J}_g^{(1)} + \bar{J}_g^{(2)} + \bar{J}_g^{(3)}$ and $\bar{M}_g^{(1)} + \bar{M}_g^{(2)} + \bar{M}_g^{(3)}$. As expected, the signature of the air/ground rough interface is significantly larger than that of the underground rough layer. Table 1 summarizes all examples considered in this section obtained using the conventional MoM, the MIM, and the MIM with the SDFMM. All these three models are calculating the surface currents on the air/ground interface and on the buried object. The overall computer memory and CPU time are given for one interaction mechanism (i.e., ground-object-ground). In Example 7, the total CPU time is 192 min — 177 min for the TFQMR iterative solver and only 15 min for updating the incident fields on both the ground and the underground layer (interactions). This represents less than 8% of the total CPU time.

† The emphasis is to validate the MIM with the MoM for these small cases.

‡ The MoM could not be used for this case due to the large memory requirements (> 6 GB).

In all results presented in this section, a relative residual error of 10^{-5} is used in the TFQMR iterative solver [17] and the smallest FMM block size is assumed to be $0.32\lambda_0 \times 0.32\lambda_0$. In Examples 1-4, upon comparing the use of the MIM with the conventional MoM, the reductions in the total CPU time and computer memory, range from 30% to 60% and from 20% to 35%, respectively. On the other hand, the CPU time and computer memory are reduced by almost 65%

and 88%, respectively, when the MIM with the SDFMM is used versus the MIM as shown in Example 5. Moreover, in Example 7, only the MIM with the SDFMM could be used due to the huge required computer memory ($>6\text{GB}$) for both the MoM and the MIM.

It is necessary to emphasize that the most attractive feature of the MIM with the SDFMM is removing the quasi-planar structure constraint to enable its use in the non-quasi-planar applications described in Fig. 2. Moreover, there are no overlapping applications that require choosing between the MIM with the SDFMM which works more efficiently for non-shallow scatterers and the complete SDFMM in [7],[8] which works more efficiently for shallow scatterers. However, to obtain the signature of the buried scatterer, the complete SDFMM in [7],[8] requires executing the computer code twice, with and without the buried object, while the MIM with the SDFMM computes the object signature by running the computer code only once. Even though no convergence problems were encountered in any of the tested cases, even when a very shallow underground layer is buried in lossless soil, however for shallow scatterers, the complete SDFMM in [7],[8] should be used since it represents a potentially non-stationary algorithm for the whole matrix as discussed in [19] in addition to its superior computational complexity when used for the whole scatterer.

IV. CONCLUSIONS

The multiple interaction approach is used with the robust SDFMM to remove the quasi-planar structure constraint to enable analyzing non-shallow objects buried beneath the 2-D random rough ground. The results show that the first interaction mechanism between the ground and the buried scatterer significantly contributes to the surface current solutions while the contributions of additional interactions become insignificant especially when the non-shallow object is buried in lossy background soil.

ABSTRACT

In this work, we present a statistical study of the electric field scattered from a 3-D penetrable object buried under a 2-D random rough surface. Monte Carlo simulations using the Steepest Descent Fast Multipole Method (SDFMM) are conducted to calculate the average and the standard deviation of the near zone scattered fields. The SDFMM, originally developed at UIUC has been modified to calculate the unknown surface currents both on the rough ground and on the buried object due to excitation by a tapered Gaussian beam. The rough ground medium used in this study is an experimentally measured typical dry Bosnian soil with 3.8% moisture, while the buried object represents a plastic land mine modeled as an oblate spheroid with dimensions

and burial depth smaller than the free space wavelength. Both vertical and horizontal polarizations for the incident waves are studied. The numerical results show that the TNT mine signature is almost 5% of the total field scattered from the ground. Moreover, relatively recognizable object signatures are observed even when the object is buried under the tail of the incident beam. Interestingly, even for the small surface roughness parameters considered here, the standard deviation of the object signature is almost 30% of the signal itself, indicating significant clutter distortion due to the roughness of the ground.

I. INTRODUCTION

For subsurface sensing applications such as indicated in Fig. 1, electromagnetic wave scattering from rough ground is a major source of clutter for the measurements. Analyzing and characterizing this clutter is vital in the development of more efficient radar sensing systems. This random scattering of the electromagnetic fields necessitates the use of Monte Carlo simulations and makes it a key stochastic process to obtain the statistics of the scattered fields, and hence to extract information and draw meaningful conclusions from the numerical results. There is much published work on electromagnetic scattering from one- or two-dimensional random rough surfaces only (without buried objects) using Monte Carlo simulations, e.g., [1]-[5]. Moreover, there are several publications that model electromagnetic waves from objects buried under one-dimensional random rough surfaces, e.g., [6]-[8], or objects buried under flat half-spaces [9]. However, there are very few published works for an object buried under a two-dimensional random rough surface; [10], which attempts to model a perfect electrically conducting (PEC) buried object and, to the author's knowledge, only [11] attempts to model the case of a penetrable buried object.

The computational expenses, the CPU time and computer memory required to calculate the scattering fields from 3-D penetrable scatterers become excessive for either an electrically large scatterer and/or a scatterer with large dielectric constant. In addition, Monte Carlo simulations require that the calculations must be repeated for many rough surface realizations (depending on the ground roughness) until results converge. As it is known, solving a 3-D scattering problem is expensive even for one surface realization, so conducting Monte Carlo simulations with hundreds of realizations without using fast algorithms is prohibitive even using supercomputers. Implementing the fast multipole method (FMM) [12]-[16] makes the solution of a 3-D problem tractable with significant reduction in CPU time and computer memory. The integral equation-based Steepest Descent Fast Multipole Method (SDFMM), a hybridization of the Moment Method (MOM), the Fast Multipole Method (FMM) and the Steepest Descent Path integration rule (SDP), is used to calculate the unknown surface currents. The details of the SDFMM are published in [17]-[20].

In this work, we are using the same formulations we developed in [11], with primary emphasis on conducting efficient and fast Monte Carlo simulations to obtain the statistics of the scattered near fields. In Section II, the problem formulations are briefly summarized. Numerical results using the SDFMM are presented in Section III. Conclusions and future work are stated in Section IV.

II. PROBLEM FORMULATION

The SDFMM makes use of the equivalence theorem to calculate the electric and magnetic fields inside and outside a 3-D penetrable object buried under the rough surface interface, details are

presented in [11]. The 3-D arbitrary object is modeled by scatterer R_3 that is immersed in scatterer R_2 which represents the rough ground. The scatterer R_2 is immersed in the free space region represented by R_1 , as shown in Fig. 2. The three regions, R_1 , R_2 and R_3 have permittivity and permeability given by ϵ_1 and μ_1 , ϵ_2 and μ_2 , and ϵ_3 and μ_3 , respectively, representing free space, soil medium and penetrable buried object. There are two final sets of unknown equivalent electric and magnetic surface currents in the following formulations. They are $\mathbf{J}_1, \mathbf{M}_1$, on the exterior of S_1 , interface between R_1 and R_2 , and $\mathbf{J}_3, \mathbf{M}_3$ on the exterior of S_2 , interface between R_2 and R_3 . Upon applying the boundary conditions, continuity of tangential components of the electric and magnetic fields on S_1 and S_2 , new integral equation formulations are obtained as [11]:

$$\mathbf{E}^{inc}(\mathbf{r})\big|_{\text{tang.}} = [(L_1 + L_2)\mathbf{J}_1 - (K_1 + K_2)\mathbf{M}_1 - L_3\mathbf{J}_3 + K_3\mathbf{M}_3]_{\text{tang.}} \quad (1)$$

$$\mathbf{H}^{inc}(\mathbf{r})\big|_{\text{tang.}} = \left[(K_1 + K_2)\mathbf{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \mathbf{M}_1 - K_3\mathbf{J}_3 - \frac{L_3}{\eta_2^2} \mathbf{M}_3 \right]_{\text{tang.}} \quad (2)$$

$$0 = [-L_2\mathbf{J}_1 + K_2\mathbf{M}_1 + (L_3 + L_4)\mathbf{J}_3 - (K_3 + K_4)\mathbf{M}_3]_{\text{tang.}} \quad (3)$$

$$0 = \left[-K_2\mathbf{J}_1 - \frac{L_2\mathbf{M}_1}{\eta_2^2} + (K_3 + K_4)\mathbf{J}_3 + \left(\frac{L_3}{\eta_2^2} + \frac{L_4}{\eta_3^2} \right) \mathbf{M}_3 \right]_{\text{tang.}} \quad (4)$$

In which the integro-differential operators L_i and K_i , $i=1, 2, 3$ and 4 , are given in detailed in [11]. In Eqs. 1-4, the unknown surface electric and magnetic currents are \mathbf{J}_1 , \mathbf{M}_1 , \mathbf{J}_3 , and \mathbf{M}_3 , while the tangential component of the incident electric and magnetic fields on the rough surface are given by $\mathbf{E}^{inc}(\mathbf{r})\big|_{\text{tang.}}$ and $\mathbf{H}^{inc}(\mathbf{r})\big|_{\text{tang.}}$, respectively. The intrinsic impedance in each region is

$\eta_i = \sqrt{\mu_i / \epsilon_i}$, $i=1, 2$, and 3 , where the dielectric permittivity and permeability in each region are ϵ_i and μ_i , respectively. Equations 1-4 are considered the extension of the PMCHW formulations that has been shown to yield a unique solution at internal resonances associated with the corresponding conducting scatterer [21]-[23]. The equivalent electric and magnetic currents are approximated using the RWG vector basis functions $\mathbf{j}(\mathbf{r})$ [21], [24] as:

$$\mathbf{J}_1(\mathbf{r}) = \sum_{n=1}^N I_{1n} \mathbf{j}_{1n}(\mathbf{r}), \quad \mathbf{M}_1(\mathbf{r}) = \eta_1 \sum_{n=1}^N I_{2n} \mathbf{j}_{1n}(\mathbf{r}), \quad \mathbf{r} \in S_1 \quad (5a)$$

$$\mathbf{J}_3(\mathbf{r}) = \sum_{m=1}^P I_{3m} \mathbf{j}_{2m}(\mathbf{r}), \quad \mathbf{M}_3(\mathbf{r}) = \eta_1 \sum_{m=1}^P I_{4m} \mathbf{j}_{2m}(\mathbf{r}), \quad \mathbf{r} \in S_2 \quad (5b)$$

where surfaces S_1 and S_2 are discretized into triangular patches with total number of edges (number of unknown coefficients) equal to N on S_1 and equal to P on S_2 . As shown in Eqs. (5a) and (5b), both the electric and magnetic surface currents has the same number of unknown coefficients (edges) on each surface. Upon applying Galerkin's method and substituting the above current approximations in Eqs. (1-4), the original integral equations are transformed into a set of linear system of equations given by:

$$\mathbf{Z}\mathbf{I} = \mathbf{V} \quad (6)$$

Notice that the matrix \mathbf{Z} has order of $2(N+P) \times 2(N+P)$, the vector \mathbf{V} is a matrix of order $2(N+P) \times 1$ and composed of a submatrix of the tested tangential incident electric field \mathbf{E}^{inc} of order $N \times 1$ and a submatrix of the tested normalized magnetic field $\eta_1 \mathbf{H}^{inc}$ of order $N \times 1$, and a null submatrix of order $2P \times 1$. Finally, the SDFMM is implemented in Eq. 6 reducing the

computational complexity for the CPU time and computer memory requirements from $O(K^2)$, for the MOM, to only $O(K)$ per iteration of iterative solver using the SDFMM [17]-[19], where $K=2(P+N)$ is the total number of the electric and magnetic surface current unknowns.

III. NUMERICAL RESULTS

The SDFMM code has been validated with the SMCG method (sparse canonical conjugate gradient method) [10] where the scatterer is a PEC sphere buried under a random rough surface and very good agreement is presented in [11]. More validations of the SDFMM code (not presented here) are conducted showing excellent agreement between the SDFMM code and both the Mie and MOM solutions for the case of just a penetrable sphere immersed in air (no rough surface) and excited by incident plane wave [21].

In all results presented in this section, the incident wave is assumed to be a Gaussian beam [25] located in the plane of incidence as shown in Fig.1. The half beam width of the Gaussian beam is assumed to be $L/5$, where the simulated rough ground has dimensions equal to $L \times L$, with $L = 8\lambda_0$ in this work. This leads to plane wave illumination of a spot size of diameter $3.2\lambda_0$ on the ground with tapered illumination towards the edges of the finite modeled ground. The rough surface is characterized with Gaussian statistics for the random heights and for the autocorrelation function. In this work, we are interested at the anti-personnel mine detection application which justifies the assumption of small roughness parameters of the ground given by the root mean square height $\sigma = 0.04\lambda_0$ and the correlation length $l_c = 0.5\lambda_0$. The dielectric constant of a typical Bosnian soil with 3.8% moisture is $\epsilon_r = 2.5 - i0.18$ at 1GHz [26], while the dielectric constant of the buried object (*TNT* material) is $\epsilon_r = 2.9 - i0.072$. The buried object is

modeled as an oblate spheroid with top view as a circle of radius $a=0.3\lambda_0$ and both front and side views are ellipses of dimensions $a=0.3\lambda_0$ and $b=0.15\lambda_0$. The burial depth of the object is $d = 0.3\lambda_0$ and is measured from its center to the mean plane of the rough surface. In this work the incident Gaussian beam is always pointing at the center of the rough ground with plane wave illumination spot of diameter equal to $3.2\lambda_0$ compared with $0.6\lambda_0$ diameter of the buried spheroid. Moreover, all results here represent near scattered electric fields and all subtraction processes are conducted with complex vectors.

In all results in this section, the discretization length of the surface current on the rough ground is assumed to be $0.08\lambda_0$ producing a total number of surface current unknowns as $2N = 59,600$ [11]. The number of nodes and patches on the buried penetrable oblate spheroid are 122 and 240, respectively, producing a total number of surface current unknowns as $2P=720$ [11]. The dimensions of the SDFMM finest block are assumed $0.32\lambda_0 \times 0.32\lambda_0$ with two blocks separating the near field (MOM) from the far field (SDFMM) interactions on the scatterer [17]-[19].

As mentioned earlier, we are primarily interested at scattered electric fields in the near zone, which can be calculated using the solved electric and magnetic surface currents [27] and are obtained at point receivers located $0.5\lambda_0$ above the nominal rough surface with resolution $0.1\lambda_0$, as shown in Fig. 1. The magnitude of the average scattered electric field and the standard deviation are calculated as:

$$Average = \left| \frac{1}{M} \sum_{i=1}^M \mathbf{E}_i \right| \quad (7a)$$

$$STD = \sqrt{\frac{1}{M} \sum_{i=1}^M |\mathbf{E}_i|^2 - \left| \frac{1}{M} \sum_{i=1}^M \mathbf{E}_i \right|^2} \quad (7b)$$

where, \mathbf{E}_i represents the complex vector electric field scattered from the i^{th} rough surface realization where $i=1, 2, \dots, M$, where the size of Monte Carlo set (M) is assumed to be 65 in all results in this section.

In Figs. 3-7, two incident elevation angles with one azimuth angle $\varphi^i = 0$, will be considered; $\vartheta^i = 0$ for the horizontally polarized incident waves where the electric field is in the y -direction (Figs. 3-6) and $\vartheta^i = 10^\circ$ for both polarizations (Figs. 7a-d).

In Figs. 3a and 3b, the magnitude of the average near scattered electric fields at $z = 0.5\lambda_0$, using Monte Carlo simulations, from the rough surface alone and from the rough surface with the buried spheroid, located at $x = y = 4.0\lambda_0$, are shown, respectively. Notice the slight difference between results in Fig. 3a and Fig. 3b, which is due to the small size of the buried object compared with the free space wavelength. Our objective is to analyze and extract information about the buried object that caused this slight difference. In Fig. 4a, the near scattered electric fields from the buried spheroid under two individual rough surface realizations selected from the 65 ones used in Fig. 3b, the average of the 65 surface realizations of rough surface with buried object (Fig. 3b), the average of the 65 surface realizations of rough surface alone (Fig. 3a), and the scattered electric field from flat ground with and without buried object are plotted at $Y = 4.0\lambda_0$. The results of Fig. 4a show the oscillations in the scattered electric fields from these individual rough surface realizations compared with the smooth curve obtained upon averaging the fields using Monte Carlo simulations. Notice that the average fields shown in Fig. 4a (solid

and dotted lines) are not perfectly symmetric around the point $X = 4.0\lambda_0$ compared with the symmetrical results of the flat ground. This can be attributed to the relatively small size of the Monte Carlo sample (65 realizations) and to the edge effect of the finite modeled rough ground. This qualitative comparison shown in Fig. 4a indicates the significant effect of the rough ground on the scattered signals even with the small roughness parameters chosen in this application. In order to obtain the scattered fields due just to the buried object, four types of subtractions are conducted with complex vectors and results are shown in Figs. 4b-e. First, we subtract the electric field scattered from flat ground alone from those scattered from flat ground with buried spheroid and results are shown in Fig. 4b. Second, we subtract the average scattered field from rough surface alone (solid curve in Fig. 4a) from the fields scattered from one rough surface realization with the buried object (surface #1 in Fig. 4a). The outcome is plotted in Fig. 4c, which shows very noisy results compared with Fig. 4b. Instead, the near electric fields scattered from only one surface realization is subtracted from those scattered from the same surface realization with buried spheroid, and results are plotted in Fig. 4d. Significant enhancement in results is shown in Fig. 4d compared with Fig. 4c giving more information about the object signature. Finally upon repeating the subtraction process of Fig. 4d for each of the 65 rough surface realizations, and then taking the statistical average of the outcome, results shown in Fig. 4e are obtained. Thus conducting Monte Carlo simulations of the 65 object signals obtained by subtraction, gives ideal image as clearly shown in Fig. 4e compared with Fig. 4b versus Figs. 4c and 4d. In practice signals scattered from a target buried under only one rough ground are measured. However the statistics shown in Fig. 4e are used to conclude that the *TNT* spheroid has signature almost equal to 5% of the total scattered fields. In reality, neither the profile of the rough ground or its soil dielectric constant is precisely known. However, if these parameters can

be estimated, then our fast model can be used to compute the scattered fields from the rough ground alone. As a result it can be used to remove the clutter from the measurement data by subtraction, as shown earlier, aiming to obtain results similar to Fig. 4d. Signal-processing techniques could be applied to this output rather than directly to the more noisy measurement data.

Upon keeping the incident Gaussian beam pointing at the center of the ground and changing the location of the buried spheroid from the center of the ground at $x = y = 4.0\lambda_0$ to $x = y = 5.0\lambda_0$ and to $x = 6.5\lambda_0, y = 4.0\lambda_0$, similar results to Fig. 4e are obtained at these locations. A qualitative comparison between the scattered electric fields from the buried spheroid versus the object location is shown in Fig. 5. As expected, these results show the degradation of object signature with respect to its closeness to the center of the incident Gaussian beam. Although the maximum excitation is not over the target, computing the difference fields clearly shows the target position. The standard deviation (*STD*) of the 65 scattered electric fields due just to the spheroid is calculated using Eq. 7b and plotted in Fig. 6 show that it is equal to almost 30% of the object signature shown in Fig. 4e. In Figs. 7a and 7b, the elevation angle of the incident Gaussian beam is varied to be $\vartheta^i = 10^\circ$, and the average scattered fields using Monte Carlo simulations are plotted for the vertical polarization from surface only and from surface with buried spheroid, respectively. Also, slight distortion is observed in the object signature at this oblique incident angle for both polarizations as shown in Figs. 7c and 7d.

The CPU time required for the SDFMM to calculate the surface current unknowns for each rough surface realization are 38 minutes to fill in the impedance matrix, 72 minutes for the

TFQMR (transpose-free quasi-minimal residual) iterative solver [28], and 3 minutes to calculate the near field scattered above the ground with $0.1\lambda_0$ resolution. The computer memory required to run the SDFMM is 950MB. These computations were conducted using one processor on Compaq GS140 EV6 machine.

As known, the size of Monte Carlo sample (number of rough surface realizations) increases dramatically with the increase of ground roughness parameters. For flat ground only one surface is needed while for very rough ground, hundreds of realizations are needed for efficient conduction of Monte Carlo simulations. The adequate sample size can be obtained by gradually increasing the number of realizations used in the calculations till no change is observed in numerical results. The CPU time dramatically increases with the increase of Monte Carlo sample size. This barrier can be eliminated by the possible parallel implementation of the SDFMM code similar to the SMCG method [29].

IV. CONCLUSIONS

We demonstrated the implementation of the SDFMM to calculate the unknown surface currents on a random rough surface with buried 3-D penetrable object. The significant speed of this algorithm allowed an efficient conduction of the Monte Carlo simulations. The average and the standard deviation of the near fields scattered from the ground with the buried object are calculated. Our results showed that the presence of the rough interface distorts the scattered fields from the buried object even for the small roughness parameters considered here. Interestingly, we also showed that the standard deviation statistic of the object signals is large relative to the signal itself. Recognizable object signature is observed even when the object is not

buried under the center of the ground where the incident Gaussian beam is pointing. Having determined some of the statistics of both clutter and target signals, it is possible to apply statistical signal processing for target detection, which is the subject of future work.

ACKNOWLEDGEMENTS

The authors would like to thank Prof. W. Chew, Prof. E. Michielssen and Dr. V. Jandhyala at UIUC for allowing them the use and modification of the SDFMM computer code for the current application. This research was sponsored by the Army Research Office Demining MURI grant # DAA 0-55-97-0013 and in part by the Engineering Research Centers Program of the National Science Foundation under award number EEC-9986821. This work benefited from the allocation of time at the Northeastern University Advanced Scientific Computation Center (NU-ASCC).

ABSTRACT

The electromagnetic scattering from a three-dimensional shallow object buried under a two-dimensional random rough dielectric surface is analyzed in this work. The buried object can be a perfect electric conductor (PEC) or can be a penetrable dielectric with size and burial depth comparable to the free space wavelength. The random rough ground surface is characterized with Gaussian statistics for surface height and for surface autocorrelation function. The PMCHW (Poggio, Miller, Chang, Harrington, and Wu) integral equations are implemented and extended in this work. The integral equation-based Steepest Descent Fast Multipole Method (SDFMM), that was originally developed at UIUC, has been used and the computer code based on this

algorithm has been successfully modified to handle the current application. The significant potential of the SDFMM code is that it calculates the unknown moment method surface electric and magnetic currents on the scatterer in a dramatically fast, efficient and accurate manner. Interactions between the rough surface interface and the buried object are fully taken into account with this new formulation. Ten incident Gaussian beams with same elevation angle and different azimuth angles are generated for excitation as a one possible way of having multiple views of a given target.

The scattered electric fields due to these ten incident beams are calculated in the near zone and their complex vector average over the multiple views is computed. The target signature is obtained by subtracting the electric fields scattered from the rough ground only from those scattered from the ground with the buried anti-personnel mine. Significant polarization dependency is observed for the PEC object signature compared with that of the penetrable object, which can be used in target discrimination. Moreover, fields scattered above the rough ground experience significantly more distortion than fields transmitted into the ground.

I. INTRODUCTION

Subsurface sensing of buried electromagnetically penetrable objects under random rough surfaces has many important applications, such as detection of mines, underground water, buried hazardous environmental waste, and underground petroleum. Modeling the wave scattering is essential for efficient sensor design and for inverse scattering and target reconstruction processing. Of particular interest here is the topic of anti-personnel landmine detection, as shown schematically in Fig. 1. The analysis of scattering and transmission of the electromagnetic waves

in the presence of a random rough dielectric interface and in the near field of the sensing systems is a crucial step for subsurface object detection problems in general and landmine remediation applications in particular. Generally, this fully three dimensional problem must be treated numerically. However the calculation of the required fields using conventional techniques (e.g. moment method, finite elements, or finite differences) is a computationally intensive undertaking especially for large dielectric constant soil. The computational complexity of the problem dramatically increases upon inserting objects under the rough interface, especially when these objects are penetrable.

To deal with this complex scenario, we apply the SDFMM, originally developed by V. Jandhyala, E. Michielssen, and W. Chew [1]-[3] to analyze 3-D scattering problems of quasi-planar structures, which is well suited to handle large computational domains of this sort. In particular, the SDFMM computer code has been successfully modified to handle objects with burial depth comparable to the wavelength and varieties of ground soil characteristics. Mine fields are located in different places all over the world where the dielectric constant of the soil significantly varies, for example, $\epsilon_r = 2.5 - i0.18$ for Bosnian soil with 3.8% moisture at 1GHz, $\epsilon_r = 5.4 - i0.04$ for Puerto Rican soil with 10% moisture at 960MHz, while $\epsilon_r = 9.18 - i1.26$ for Bosnian soil with 25% moisture at 1GHz. These modifications and their use in calculating scattering simulations are presented in this work. The SDFMM is a hybridization of three methods: the Method of Moments (MOM), the Steepest Descent Path (SDP) method, and the Fast Multipole Method (FMM). The basic concept of the SDFMM is to subdivide the rough surface and the buried object scatterers into small groups and each group includes some of the moment method surface current unknowns. The interactions between these current unknowns in

a given group or in nearby groups are calculated using the standard MOM, which incorporates multiplying the elements of the impedance matrix by the current coefficient vector. All other interactions are calculated in one step without conducting matrix vector multiplication by using the fast multipole method, which is also hybridized with the SDP integration rule. The details of the SDFMM can be found in [1]-[6].

In section II, we present the analysis of the problem based on extending the implementation of the PMCHW [7] integral equations for the three regions; air, soil, and buried object. The object can either be penetrable, as characterized by its dielectric constant, or a PEC. In section III, the numerical results for the electric fields in the near zone are shown. Conclusions and future work will be summarized in Section IV. The proof of an important and useful identity used in the computations is given in Appendix A.

II. FORMULATION

In this section, we formulate the problem of a penetrable arbitrary 3-D scatterer R_2 immersed in R_1 with an interior scatterer of different material R_3 as shown in Fig. 2a. The three regions, R_1 , R_2 and R_3 have permittivity and permeability given by ϵ_1 and μ_1 , ϵ_2 and μ_2 , and ϵ_3 and μ_3 , respectively. As shown in Figs. 2a-d, the region R_2 is bounded by surfaces S_1 (exterior) and S_2 (interior) with normal vectors \bar{n}_1 and \bar{n}_2 on S_1 and, \bar{n}_3 and \bar{n}_4 on S_2 . The region R_3 is bounded by surface S_2 . The normal vectors \bar{n}_1 , \bar{n}_2 and \bar{n}_3 , and \bar{n}_4 are chosen to point toward regions R_1 , R_2 , and R_3 , respectively. The electric and magnetic fields in regions R_1 , R_2 , and R_3 are \bar{E}_1, \bar{H}_1 , due to equivalent currents \bar{J}_1, \bar{M}_1 , as shown in Fig. 2b, \bar{E}_2, \bar{H}_2 due to equivalent currents

\bar{J}_2, \bar{M}_2 and \bar{J}_3, \bar{M}_3 , as shown in Fig. 2c, and \bar{E}_3, \bar{H}_3 , due to equivalent currents \bar{J}_4, \bar{M}_4 , as shown in Fig. 2d. Following the analysis in [7], [9], [10] with time dependence $\exp(i\omega t)$ assumed, the electric and magnetic fields at an arbitrary point \bar{r} in region R_1 are:

$$\theta_1(\bar{r})\bar{E}_1(\bar{r}) = \bar{E}^{inc}(\bar{r}) - \int_{S_1} (i\omega\mu_1(\bar{n}_1 \times \bar{H}_1)\Phi_1 - (\bar{n}_1 \times \bar{E}_1) \times \nabla'\Phi_1 - (\bar{n}_1 \cdot \bar{E}_1)\nabla'\Phi_1) ds' \quad (1a)$$

$$\theta_1(\bar{r})\bar{H}_1(\bar{r}) = \bar{H}^{inc}(\bar{r}) + \int_{S_1} (i\omega\epsilon_1(\bar{n}_1 \times \bar{E}_1)\Phi_1 + (\bar{n}_1 \times \bar{H}_1) \times \nabla'\Phi_1 + (\bar{n}_1 \cdot \bar{H}_1)\nabla'\Phi_1) ds' \quad (1b)$$

Similarly, the electric and magnetic fields in region R_2 are:

$$\begin{aligned} \theta_2(\bar{r})\bar{E}_2(\bar{r}) = & - \int_{S_1} (i\omega\mu_2(\bar{n}_2 \times \bar{H}_2)\Phi_2 - (\bar{n}_2 \times \bar{E}_2) \times \nabla'\Phi_2 - (\bar{n}_2 \cdot \bar{E}_2)\nabla'\Phi_2) ds' \\ & - \int_{S_2} (i\omega\mu_2(\bar{n}_3 \times \bar{H}_2)\Phi_2 - (\bar{n}_3 \times \bar{E}_2) \times \nabla'\Phi_2 - (\bar{n}_3 \cdot \bar{E}_2)\nabla'\Phi_2) ds' \end{aligned} \quad (1c)$$

$$\begin{aligned} \theta_2(\bar{r})\bar{H}_2(\bar{r}) = & \int_{S_1} (i\omega\epsilon_2(\bar{n}_2 \times \bar{E}_2)\Phi_2 + (\bar{n}_2 \times \bar{H}_2) \times \nabla'\Phi_2 + (\bar{n}_2 \cdot \bar{H}_2)\nabla'\Phi_2) ds' \\ & + \int_{S_2} (i\omega\epsilon_2(\bar{n}_3 \times \bar{E}_2)\Phi_2 + (\bar{n}_3 \times \bar{H}_2) \times \nabla'\Phi_2 + (\bar{n}_3 \cdot \bar{H}_2)\nabla'\Phi_2) ds' \end{aligned} \quad (1d)$$

Finally, the electric and magnetic fields in region R_3 , are:

$$\theta_3(\bar{r})\bar{E}_3(\bar{r}) = - \int_{S_2} (i\omega\mu_3(\bar{n}_4 \times \bar{H}_3)\Phi_3 - (\bar{n}_4 \times \bar{E}_3) \times \nabla'\Phi_3 - (\bar{n}_4 \cdot \bar{E}_3)\nabla'\Phi_3) ds' \quad (1e)$$

$$\theta_3(\bar{r})\bar{H}_3(\bar{r}) = \int_{S_2} (i\omega\epsilon_3(\bar{n}_4 \times \bar{E}_3)\Phi_3 + (\bar{n}_4 \times \bar{H}_3) \times \nabla'\Phi_3 + (\bar{n}_4 \cdot \bar{H}_3)\nabla'\Phi_3) ds' \quad (1f)$$

In Eqs. 1a-f, \bar{r} is the field point, \bar{r}' is the source point, and Φ_i is the 3-D scalar Green's function

$\exp(-ik_i|\bar{r} - \bar{r}'|)/4\pi|\bar{r} - \bar{r}'|$ in which $k_i = \omega\sqrt{\epsilon_i\mu_i}$ is the wave number in each region, $i=1, 2$ and

3. The symbol $\theta_i(\bar{r})$ is the Heaviside function that gives the jump condition at surface S ,

$(\theta_i(\bar{r})=1 \text{ for } \bar{r} \in R_i, 0.5 \text{ for } \bar{r} \in \partial R_i, 0 \text{ otherwise})$ [7], [9], [10], where the symbol ∂R_i

represents the boundary of region R_i . The equivalent currents \bar{J}_1 and \bar{M}_1 are related to the

tangential electric and magnetic field components in region R_1 as $\bar{J}_1 = \bar{n}_1 \times \bar{H}_1|_{S_1}$ and $\bar{M}_1 = \bar{E}_1 \times \bar{n}_1|_{S_1}$. Similarly, the equivalent currents $\bar{J}_2, \bar{J}_3, \bar{J}_4, \bar{M}_2, \bar{M}_3$, and \bar{M}_4 can be related to tangential electric and magnetic fields on S_1 and S_2 . Moreover, the normal electric and magnetic field components in region R_1 are related to the equivalent currents as $\bar{n}_1 \cdot \bar{E}_1 = -\nabla \cdot \bar{J}_1 / i\omega\epsilon_1$ and $\bar{n}_1 \cdot \bar{H}_1 = -\nabla \cdot \bar{M}_1 / i\omega\mu_1$. Similarly, the normal electric and magnetic field components in regions R_2 and R_3 can be expressed as functions of their associated equivalent currents. Applying the boundary conditions for the tangential electric and magnetic field components on surface S_1 leads to $\bar{J}_1 = -\bar{J}_2$ and $\bar{M}_1 = -\bar{M}_2$, and on surface S_2 leads to $\bar{J}_3 = -\bar{J}_4$ and $\bar{M}_3 = -\bar{M}_4$. Thus, upon equating the tangential component of the electric fields (\bar{E}_1 and \bar{E}_2) and magnetic fields (\bar{H}_1 and \bar{H}_2), on surface S_1 , we get:

$$\bar{E}^{inc}(\bar{r})|_{\text{tang.}} = [(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 - L_3\bar{J}_3 + K_3\bar{M}_3]_{\text{tang.}} \quad (2)$$

$$\bar{H}^{inc}(\bar{r})|_{\text{tang.}} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 - K_3\bar{J}_3 - \frac{L_3}{\eta_2^2} \bar{M}_3 \right]_{\text{tang.}} \quad (3)$$

and on surface S_2 , we get:

$$0 = [-L_2\bar{J}_1 + K_2\bar{M}_1 + (L_3 + L_4)\bar{J}_3 - (K_3 + K_4)\bar{M}_3]_{\text{tang.}} \quad (4)$$

$$0 = \left[-K_2\bar{J}_1 - \frac{L_2\bar{M}_1}{\eta_2^2} + (K_3 + K_4)\bar{J}_3 + \left(\frac{L_3}{\eta_2^2} + \frac{L_4}{\eta_3^2} \right) \bar{M}_3 \right]_{\text{tang.}} \quad (5)$$

where, operators L_j and $K_j, j=1, 2, 3$ and 4, are given by:

$$L_{1,2}\bar{X} = \int_{S_1} \left\{ i\omega\mu_{1,2}\Phi_{1,2}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{1,2}} \nabla \nabla' \cdot \bar{X}(\bar{r}') \Phi_{1,2} \right\} ds' \quad (6a)$$

$$L_{3,4}\bar{X} = \int_{S_2} \left\{ i\omega\mu_{2,3}\Phi_{2,3}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{2,3}}\nabla\nabla'\cdot\bar{X}(\bar{r}')\Phi_{2,3} \right\} ds' \quad (6b)$$

$$K_{1,2}\bar{X} = \int_{S_1} \bar{X}(\bar{r}') \times \nabla\Phi_{1,2} ds' \quad (6c)$$

$$K_{3,4}\bar{X} = \int_{S_2} \bar{X}(\bar{r}') \times \nabla\Phi_{2,3} ds' \quad (6d)$$

The vector \bar{X} represents the surface electric current \bar{J} and/or the surface magnetic current \bar{M} on surface S_1 or on surface S_2 . The intrinsic impedance in each region is $\eta_i = \sqrt{\mu_i/\epsilon_i}$, where the dielectric permittivity and permeability are ϵ_i and μ_i , respectively. Equations 2-5 are considered the extension of the PMCHW formulation which has been shown to yield a unique solution at internal resonances associated with the corresponding conducting scatterer [7], [11], [12].

The equivalent electric and magnetic currents $\bar{J}_{1,3}$ and $\bar{M}_{1,3}$ on S_1 and on S_2 , are approximated in Eqs. 2-5 using the RWG vector basis functions $\bar{j}(\bar{r})$ [7], [8] as follows

$$\bar{J}_1(\bar{r}) = \sum_{n=1}^N I_{1n} \bar{j}_{1n}(\bar{r}), \quad \bar{M}_1(\bar{r}) = \eta_1 \sum_{n=1}^N I_{2n} \bar{j}_{1n}(\bar{r}), \quad \bar{r} \in S_1 \quad (7a)$$

$$\bar{J}_3(\bar{r}) = \sum_{m=1}^P I_{3m} \bar{j}_{2m}(\bar{r}), \quad \bar{M}_3(\bar{r}) = \eta_1 \sum_{m=1}^P I_{4m} \bar{j}_{2m}(\bar{r}), \quad \bar{r} \in S_2 \quad (7b)$$

where η_1 is the intrinsic impedance of region R_1 , which is the free space in this work. For the sake of computational efficiency, both magnetic currents \bar{M}_1 and \bar{M}_3 are normalized with the same value of η_1 as shown in Eqs. 7a and 7b. The number of the unknown coefficients on surface S_1 with coefficient vectors I_1 and I_2 , which are associated with \bar{J}_1 and \bar{M}_1 , is denoted by N ,

while the number of the unknown coefficients on surface S_2 with coefficient vectors I_3 and I_4 , associated with \bar{J}_3 and \bar{M}_3 , is denoted by P , in Eqs. 7a and 7b. Next, we substitute Eqs. 7a and 7b in Eqs. 2-5, along with multiplying the H -field equations, Eqs. 3 and 5, by the same normalizing intrinsic impedance η_1 . Upon applying Galerkin's method for testing the E - and H -field equations, the original integral equations are thus transformed into a set of linear equations $\bar{\bar{Z}}\bar{I} = \bar{V}$ given by:

$$\begin{pmatrix} \bar{Z}_{11} & \bar{Z}_{12} \\ \bar{Z}_{21} & \bar{Z}_{22} \end{pmatrix} \begin{pmatrix} I^1 \\ I^2 \end{pmatrix} = \begin{pmatrix} \bar{V}_1 \\ 0 \end{pmatrix} \quad (8)$$

where, \bar{Z}_{11} is a submatrix of order $2N \times 2N$ which represents interactions between elements only on surface S_1 , \bar{Z}_{12} is a submatrix of order $2N \times 2P$ which represents interactions between elements on surface S_1 and elements on surface S_2 , \bar{Z}_{21} is a submatrix of order $2P \times 2N$ which represents interactions between elements on surface S_2 and elements on surface S_1 , and \bar{Z}_{22} is a submatrix of order $2P \times 2P$ which represents interactions between elements only on surface S_2 . Thus the total matrix $\bar{\bar{Z}}$ has order of $2(N+P) \times 2(N+P)$. Note that the vector \bar{V}_1 is a submatrix of order $2N \times 1$ and composed of the tested tangential incident electric field \bar{E}^{inc} and the tested normalized magnetic field $\eta_1 \bar{H}^{inc}$ on surface S_1 . The unknown current coefficients I^1 and I^2 are submatrices of order $2N \times 1$ and $2P \times 1$. The elements of the submatrix \bar{Z}_{11} are given by

$$\bar{Z}_{11} = \begin{pmatrix} \langle \bar{j}_1, (L_1 + L_2) \bar{j}_1 \rangle_{S_1} & \langle \bar{j}_1, -\eta_1 (K_1 + K_2) \bar{j}_1 \rangle_{S_1} \\ \langle \bar{j}_1, \eta_1 (K_1 + K_2) \bar{j}_1 \rangle_{S_1} & \left\langle \bar{j}_1, \eta_1^2 \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{j}_1 \right\rangle_{S_1} \end{pmatrix} \quad (9a)$$

in which $\langle \bar{A}, \bar{B} \rangle_s = \int_S \bar{A}^* \cdot \bar{B} ds$ denotes the complex inner product between vector functions \bar{A}

and \bar{B} on a surface S [7]. Similarly, the elements of the submatrices \bar{Z}_{12} , \bar{Z}_{21} , and \bar{Z}_{22} are:

$$\bar{Z}_{12} = \begin{pmatrix} \langle \bar{j}_1, -L_3 \bar{j}_2 \rangle_{S_1} & \langle \bar{j}_1, \eta_1 K_3 \bar{j}_2 \rangle_{S_1} \\ \langle \bar{j}_1, -\eta_1 K_3 \bar{j}_2 \rangle_{S_1} & \left\langle \bar{j}_1, -\eta_1^2 \left(\frac{L_3}{\eta_2^2} \right) \bar{j}_2 \right\rangle_{S_1} \end{pmatrix} \quad (9b)$$

$$\bar{Z}_{21} = \begin{pmatrix} \langle \bar{j}_2, -L_2 \bar{j}_1 \rangle_{S_2} & \langle \bar{j}_2, \eta_1 K_2 \bar{j}_1 \rangle_{S_2} \\ \langle \bar{j}_2, -\eta_1 K_2 \bar{j}_1 \rangle_{S_2} & \left\langle \bar{j}_2, -\eta_1^2 \left(\frac{L_2}{\eta_2^2} \right) \bar{j}_1 \right\rangle_{S_2} \end{pmatrix} \quad (9c)$$

$$\bar{Z}_{22} = \begin{pmatrix} \langle \bar{j}_2, (L_3 + L_4) \bar{j}_2 \rangle_{S_2} & \langle \bar{j}_2, -\eta_1 (K_3 + K_4) \bar{j}_2 \rangle_{S_2} \\ \langle \bar{j}_2, \eta_1 (K_3 + K_4) \bar{j}_2 \rangle_{S_2} & \left\langle \bar{j}_2, \eta_1^2 \left(\frac{L_3}{\eta_2^2} + \frac{L_4}{\eta_3^2} \right) \bar{j}_2 \right\rangle_{S_2} \end{pmatrix} \quad (9d)$$

Notice that there are symmetrical relationships between some of the sixteen submatrices in Eqs. (9a-d), for example, it can be proven that (Appendix A):

$$\langle \bar{j}_1, \eta_1 K_3 \bar{j}_2 \rangle_{S_1} = -\langle \bar{j}_2, -\eta_1 K_2 \bar{j}_1 \rangle_{S_2} \quad (10)$$

This leads to computing and storing elements of only nine out of the above sixteen submatrices, to gain significant reduction in CPU time and computer memory requirements for the MOM part.

To obtain the formulations for a PEC interior scatterer S_2 , we delete P rows and P columns from the total matrix $\bar{\bar{Z}}$ starting from index $(2N+P+1)$ up to index $(2N+2P)$. Moreover, P rows should be deleted from vectors \bar{I} and \bar{V} starting from index $(2N+P+1)$ up to index $(2N+2P)$. This leads to a new matrix $\bar{\bar{Z}}$ that has an order of $(2N+P) \times (2N+P)$.

The objective of the above analysis is to solve Eq. 8 for the unknown current coefficients I^1 and I^2 . Upon substituting the obtained coefficients into Eq. 7a and b, the surface electric and magnetic currents can be obtained on the exterior scatterer S_1 and on the interior scatterer S_2 . Thus complex vector electric fields in the near zone can be obtained [13].

As is well known, solving the system of equations in Eq. 8 by using the MOM requires computing, storing and multiplying a full dense matrix of order $2(N+P) \times 2(N+P)$ by a vector of order $2(N+P)$, which is computationally prohibitive for large-scale scatterers even using supercomputers. This necessitates the need for the SDFMM, which makes these computations significantly tractable. Applying the SDFMM to Eq. 8, the matrix $\bar{\bar{Z}}$ is divided as $\bar{\bar{Z}}^{NF} + \bar{\bar{Z}}^{FF}$, where $\bar{\bar{Z}}^{NF}$ represents the dense near field part, and $\bar{\bar{Z}}^{FF}$ represents the sparse far field part of matrix $\bar{\bar{Z}}$. The entries of $\bar{\bar{Z}}^{NF}$ are computed directly, and then the matrix vector multiply is conducted following the conventional MOM method. The entries of $\bar{\bar{Z}}^{FF}$ are not directly computed nor stored as before, but the matrix vector multiply is conducted in one step using the inhomogeneous plane wave expansions. The interaction decomposition into near field, NF , and far field, FF , is assumed according to the distance, in wavelength, between those interacting elements on the scatterer. We should mention that the computational complexity of the SDFMM for the CPU time and the memory requirement are of $O(K)$ per iteration of the iterative solver, while they are of order $O(K^2)$ for the MOM method, where K is the total number of the surface current unknowns and it is equal to $2(N+P)$ for the buried penetrable object case [1]-[6].

III. NUMERICAL RESULTS

In this work, the exterior closed scatterer S_1 is excited with an incident Gaussian beam that induces stronger surface currents on a localized area of the surface and weaker currents away from that area [14], [15]. As a result, these surface currents become negligible on the back of the closed surface S_1 , which makes it possible to approximate S_1 by an open rough surface with dimensions $L \times L$. In all results here, L is chosen to be $8\lambda_0$ where λ_0 is the free space wavelength. In reality, the rough surface is an infinite surface, but by using a carefully tapered incident Gaussian beam, the edge effect of the modeled finite surface can be eliminated. The random rough surface, characterized by Gaussian statistics for the random heights and for the autocorrelation function, is generated using the computer random number generator [16] and will be described by the root mean square height σ and the correlation length l_c . The interior scatterer S_2 is representing the object, which is always buried at the center of the ground with burial depth measured from its center to the mean plane of the rough surface.

In Figs. 3a and b, the SDFMM computer code is compared with the sparse matrix canonical grid (SMCG) method published in [14]. The buried object is assumed to be a PEC sphere of radius $r = 0.3\lambda_0$ at burial depth $d = 0.6\lambda_0$, where the incident angle is $\vartheta^i = 20^\circ$ and the relative dielectric constant of the soil is $\epsilon_r = 2.0 - i0.2$. The HH-polarization results for the normalized radar cross section (RCS) is shown for the rough surface ($\sigma = 0.02\lambda_0$ and $l_c = 0.5\lambda_0$) without the buried PEC sphere in Fig. 3a and with the buried PEC sphere in Fig. 3b. The horizontal axis in Fig. 3 is the scatter angle θ (elevation angle in degrees) measured from the z -axis. For comparison purpose with [14], the rough surface is sampled at 8 points per λ_0 leading to a number of surface

current unknowns $N=12,160$ as in [14]. The PEC sphere is sampled at 20 points in the ϕ -direction ($0-360^\circ$) and 10 points in the ϑ -direction ($0-90^\circ$) leading to a number of surface current unknowns $P=480$. The normalized RCS is calculated by taking the average of those values produced using ten azimuth angles. The excellent agreement shown in these figures validates the SDFMM code for the buried PEC object under the rough ground.

Next, new analysis of a buried penetrable or PEC oblate spheroid of dimensions $a=0.3\lambda_0$ and $b=0.15\lambda_0$, as shown in Fig. 1, is presented. To assure accuracy, the rough surface is sampled at 12.5 points per λ_0 with a number of surface current unknowns equal to $N=29,800$. The spheroid is sampled at 20 points in the ϕ -direction and 8 points in the ϑ -direction corresponding to $P=360$ surface current unknowns.

In Figs. 4a-d, the magnitude of the complex vector electric field in the near zone is calculated at height $z=0.5\lambda_0$ above and below the nominal ground and at (x, y) grid points of resolution equal to $0.1\lambda_0$. The ground surface is rough with $\sigma = 0.04\lambda_0$, $l_c = 0.5\lambda_0$, and relative dielectric constant $\epsilon_r = 2.5 - i0.18$ which is a typical Bosnian dry (3.8% moisture) clay loam at 1GHz [17]. To enhance target detection, the near scattered electric field is computed and averaged over multiple views each pointed to the same ground point directly over the target. Ten incident Gaussian beams with same elevation angle $\vartheta^i = 10^\circ$ and different azimuth angles $\phi^i = 0, 36, 72, \dots, 324^\circ$, are simulated as suggested by Zhang, Tsang and Pak [14]. The rationale of averaging over these multiple views is that this process minimizes the clutter effect of the rough surface on individual scattered beams. In Figs. 4a and 4b, the magnitude of the near electric field

scattered from the rough surface only is plotted for the H- and V- incident polarization, respectively, while in Figs. 4c and 4d, the near electric field transmitted into the same rough ground is plotted for the H- and V- polarizations, respectively. The shown results in Figs. 4a and 4b indicate the difference in the scattered electric fields upon changing the polarization of the incident Gaussian beam (H and V). Notice that in the H-polarization at oblique incident angle $\vartheta^i = 10^\circ$, the incident electric field always has a single component perpendicular to the plane of incidence (y-component for $\phi^i = 0, \pi$), while it has two components (x- and z- for $\phi^i = 0, \pi$) in the V-polarization. Accordingly, the local reflection and transmission coefficients on each point on the rough surface are different, giving rise to the difference observed between Figs. 4a and 4b and between Figs. 4c and 4d. As seen in Figs. 4a and 4b, the scattered electric fields for each polarization appear to have ten lobes, one every 36° in azimuth direction (as seen clearly at the 0.062 V/m contour level). For a perfectly flat surface, the scattered pattern would have ten-folded symmetry, but for the rough surface, the random variations distort this pattern. As expected, the transmitted electric fields shown in Figs. 4c and 4d are larger than the scattered electric fields shown in Figs. 4a and 4b due to the relatively small value of the dielectric constant ($\epsilon_r = 2.5 - i0.18$). Moreover, the results show that the electric fields transmitted into the ground are less distorted than the scattered electric fields. This is because the local transmitted angle is smaller than the local incident angle.

The near electric field scattered from the oblate PEC spheroid buried at depth $d = 0.3\lambda_o$ is calculated for the H- and V-incident polarizations. The results obtained are only slightly different from those presented in Figs. 4a and 4b, therefore they are not presented here. The near electric field scattered due just to the object, obtained by subtracting the electric fields scattered from the

surface only (Figs. 4a and 4b) from the electric fields scattered from the surface with the buried object, is shown in Figs. 5a and 5b for H- and V-polarization, respectively. The results indicate that the signature of the buried oblate PEC spheroid is smaller than the ground scattered field, since the target is small compared with the wavelength, and is a polarization dependent, as expected, with almost four times larger magnitude V-polarization than H-polarization.

The oblate penetrable spheroid with the relative dielectric constant of TNT $\epsilon_r=2.9-i0.07$, is buried under the same rough surface as before at the same depth $d=0.3\lambda_0$. The near electric scattered fields due just to the oblate penetrable spheroid are shown in Figs. 6a and 6b for H- and V- polarization, respectively. These results indicate that the signature of the oblate penetrable spheroid is not as polarization dependent as that of the oblate PEC spheroid shown in Figs. 5a and 5b. Since the Gaussian beams on opposite sides of the object are oppositely polarized, electric fields scattered from the centered object tend to cancel. It is interestingly to note that the rough ground surface perturbs this destructive interference. The average scattered electric field from the PEC object illuminated by V-polarized beams (Fig. 5b) is greater than for the H-polarized beams (Fig. 5a), due to constructive interference of the z-components. If a progressive phase of $2\pi/10$ is successively applied to each of the scattered electric fields to focus the field at the center, stronger but almost equal signatures of the PEC object are observed in both polarizations providing a stronger but less discriminative detecting technique.

The iterative solver TFQMR [18] has been used with tolerance 1% for all obtained results. Five levels in the fast multilevel multipole part of the SDFMM with finest block size equal to $0.5025\lambda_0$ were employed here. For the oblate penetrable spheroid case, the SDFMM code

needed two CPU hours, using one processor on Compaq GS140 EV6 machine, for the iterative solver to converge for each incident beam and additional thirty-five minutes for the set up time. Thus the total required CPU time, for ten multiple views, is 20.6 CPU hours. The required computer memory is 800MB. For the oblate PEC buried spheroid, the SDFMM code needed 1.6 CPU hours per view for the iterative solver and almost the same set up time as before leading to total time of 16.5 CPU hours in this case. The required computer memory in later case was 600MB. For the rough surface only, the SDFMM code needed 0.9 CPU hours for the iterative solver, half an hour for set up time, and 500MB computer memory.

IV. CONCLUSIONS

In this paper, a study has been presented for 3-D electromagnetic scattering from shallow objects buried under the random rough surface. Our analysis is not limited to any particular incident waves, transmitter position, near or far field zone, object's geometry, nor to the Gaussian statistics characterization of the rough surface. There is a limitation, however, on the rough surface root mean square height and on the burial depth of the object due to the constraint of the SDFMM to quasi-planar structures. In the current application, this is not a major limitation since the surface root mean square height and the burial depth of the object are comparable to the free space wavelength as a typical case for antipersonnel mine detection application. The ultimate objective of our research is to distinguish between the target signal scattered from the buried object and the clutter signal scattered from the rough ground. As our numerical results show, only a slight difference can be observed between these two signals because of the small size and dielectric contrast of the buried target with respect to the surrounding soil. Even though subtracting the two signals could clearly lead to the target signal, it is not a practical detection

method. With the insight gained from the numerical simulations, we aim to derive methods to remove the clutter signal to achieve target detection with minimum "false alarms". Ongoing research using these numerical simulations tests advanced and robust signal processing techniques and provides a basis to optimize transmitter/receiver positions for best target detection. Interestingly, our results show that the scattered electric fields above the ground undergoes strong distortion compared with the electric fields transmitted into the ground. Moreover, employing multiple views of the target using ten simultaneous incident Gaussian beams has lead to strong polarization dependency only for the PEC object, which can be used in target discrimination.

ACKNOWLEDGEMENTS

The authors would like to thank Prof. W. Chew and Prof. E. Michielssen at UIUC for allowing them the use and modification of the SDFMM computer code for the current application. This work benefited from the allocation of time at the Northeastern University Advanced Scientific Computation Center (NU-ASCC). This research was sponsored by the Army Research Office Demining MURI grant # DAA 0-55-97-0013 and in part by the Engineering Research Centers Program of the NSF under award number EEC-9986821.

Appendix A

The LHS of Eq. 10 can be written as

$$\begin{aligned}\langle \bar{j}_1, \eta_1 K_3 \bar{j}_2 \rangle_{S_1} &= \eta_1 \int_{S_1} \bar{j}_1(\bar{r}) \cdot \left(\int_{S_2} \bar{j}_2(\bar{r}') \times \nabla \Phi_2(|\bar{r} - \bar{r}'|) ds' \right) ds \\ &= -\eta_1 \int_{S_1} \int_{S_2} \bar{j}_2(\bar{r}) \cdot (\bar{j}_1(\bar{r}') \times \nabla \Phi_2(|\bar{r} - \bar{r}'|)) ds' ds\end{aligned}\quad (A1)$$

where \bar{r}' is the vector position on S_2 and \bar{r} is the vector position on S_1 . From the RHS of Eq.

10, with using $\nabla \Phi = -\nabla' \Phi$, we get

$$\begin{aligned}-\langle \bar{j}_2, -\eta_1 K_2 \bar{j}_1 \rangle_{S_2} &= \eta_1 \int_{S_2} \bar{j}_2(\bar{r}) \cdot \left(\int_{S_1} \bar{j}_1(\bar{r}') \times \nabla \Phi_2(|\bar{r} - \bar{r}'|) ds' \right) ds \\ &= -\eta_1 \int_{S_2} \int_{S_1} \bar{j}_2(\bar{r}) \cdot (\bar{j}_1(\bar{r}') \times \nabla' \Phi_2(|\bar{r} - \bar{r}'|)) ds' ds\end{aligned}\quad (A2)$$

where \bar{r}' is the vector position on S_1 and \bar{r} is the vector position on S_2 . Upon renaming \bar{r}' by \bar{r} , and vice versa, and exchanging the order of integrations in Eq. A2, we get

$$\begin{aligned}-\langle \bar{j}_2, -\eta_1 K_2 \bar{j}_1 \rangle_{S_2} &= -\eta_1 \int_{S_2} \int_{S_1} \bar{j}_2(\bar{r}') \cdot (\bar{j}_1(\bar{r}) \times \nabla \Phi_2(|\bar{r} - \bar{r}'|)) ds ds' \\ &= -\eta_1 \int_{S_1} \int_{S_2} \bar{j}_2(\bar{r}') \cdot (\bar{j}_1(\bar{r}) \times \nabla \Phi_2(|\bar{r} - \bar{r}'|)) ds' ds\end{aligned}\quad (A3)$$

Notice that Eq. A3 is equivalent to Eq. A1, which proves Eq. 10. Thus the only nine submatrices computed and stored here are: three submatrices in \bar{Z}_{11} , three submatrices in \bar{Z}_{22} , two submatrices in \bar{Z}_{12} , and one submatrix in \bar{Z}_{21} .

ABSTRACT

New formulations are presented to analyze the near electric field scattered from two penetrable shallow objects buried under two-dimensional randomly rough surface. These two objects could have different materials, shapes and/or orientations; in addition their separation distance may range from a fraction of a wavelength to several wavelengths. The fast algorithm, Steepest Descent Fast Multipole Method (SDFMM), is used to compute the unknown electric and magnetic surface currents on the rough air-ground interface and on both the buried objects. Parametric investigation is presented to study the effect of the objects proximity, orientations, materials, shapes, the polarization of the incident waves, and the roughness of the ground on the scattered fields. A significant interference is observed between the two objects when they are separated by less than one free space wavelength. Moreover, even when the clutter due to the rough ground is removed, the return from the second object, can be dominating causing a possible false alarm in detecting the target. However, when all sources of clutter are removed, by removing the return from both the rough ground and the second object, the signature of the target can be clearly observed and analyzed. Our results show that the observed distortion in the target signature significantly increases with the increase of the ground roughness.

Keywords: Rough surface scattering, computational electromagnetics, buried objects.

INTRODUCTION

Several research works, in the frequency and/or in the time domain, have been published in the area of sensing objects buried under and/or above the Earth's surface. Some of the published work is related to objects buried in random media to simulate the clutter (no presence of a rough or planar interface) [1], in other work, the air-ground interface has been completely ignored justified by the very nearby position of the transmitting/receiving antennas to the ground [2], and in other several publications the roughness of the Earth's surface has been completely ignored by assuming a planar half space, where the objects are either buried under the interface [3]-[9], partially immersed in a semi-infinite dielectric medium [10] or located above the half space [11]. Interesting radar images for targets buried under planar and or rough ground are published in [12]-[15]. It is known that the roughness of the ground is a major source of clutter for target detection, however, due to its complicated analysis, several researchers have assumed that the interface is rough only in one-dimension (i.e., 2-D scattering problem) [16]-[23] where there was either a PEC (perfectly electric conducting) or a penetrable (dielectric) cylindrical target buried under the rough interface. In reality, the Earth's surface is rough in two-dimensions, which added more complexity to the analysis of the problem as in [24] where the buried target is a PEC sphere, in [25]-[26] where the object is located above the interface, and in [27]-[28] where the buried target is a penetrable and/or PEC spheroid. Recent experimental work is conducted [29] to discriminate landmines from various clutter items using EMI (electromagnetic induction). Even though, the author in [29] has concentrated his investigations on using the EMI, however the concept of discrimination between targets (not only landmines) and clutter items is the motivation of this work, which can benefit several electromagnetic subsurface sensing applications. For example, but not limited to, detection of cancerous tumors in the human breast,

plastic anti-personnel or metallic anti-tank mines, or the location of hazardous environmental waste, etc. In reality, these targets may be located next to other objects, either a second target or a clutter item. In this work, the emphasis will be on sensing two dielectric objects buried under a two-dimensional random rough ground, see Fig. 1. To the best of our knowledge, this application has not been analyzed before due its computational complexity that lead to excessive computational requirements. Therefore the Steepest Descent Fast Multipole Method (SDFMM), originally was developed at the University of Illinois at Urbana-Champaign [30]-[33], is used in this work to make these computations tractable. The new mathematical formulations are derived in Section II, numerical results are presented in Section III and concluding remarks are given in Section IV. More details are given in Appendices A and B.

II. FORMULATION

The electromagnetic waves are used to excite electric and magnetic surface currents on an exterior surface (e.g. rough ground) and consequently, due to wave penetration into the surface, currents are excited on the two interior surfaces (e.g. buried objects). The equivalence theorem is applied to express the electric and the magnetic fields as functions of surface electric and magnetic currents. There are four different regions involved in the current problem as R_1 , R_2 , R_3 and R_4 with permittivity and permeability given by ϵ_1 and μ_1 , ϵ_2 and μ_2 , ϵ_3 and μ_3 , and ϵ_4 and μ_4 , respectively, as shown in Fig.2a-e. Two interior scatterers of different materials R_3 and R_4 are immersed in the arbitrary penetrable 3-D scatterer R_2 , which is immersed in region R_1 as shown in Fig. 2a. The region R_2 is bounded by surfaces S_1 (exterior), and S_2 and S_3 (interiors) with normal vectors \bar{n}_1 and \bar{n}_2 on S_1 , \bar{n}_3 and \bar{n}_4 on S_2 , and \bar{n}_5 and \bar{n}_6 on S_3 , see Fig. 2a-e.

While regions R_3 and R_4 are bounded by surfaces S_2 and S_3 , respectively, as shown in Figs.

2d-e. The normal vectors (\bar{n}_1) , $(\bar{n}_2, \bar{n}_3$ and $\bar{n}_4)$, (\bar{n}_5) and (\bar{n}_6) are assumed to point into regions

R_1, R_2, R_3 , and R_4 respectively. The electric and magnetic fields in regions R_1, R_2, R_3 and R_4

are (\bar{E}_1, \bar{H}_1) , (\bar{E}_2, \bar{H}_2) , (\bar{E}_3, \bar{H}_3) and (\bar{E}_4, \bar{H}_4) which are due to equivalent currents (\bar{J}_1, \bar{M}_1) ,

$(\bar{J}_2, \bar{M}_2, \bar{J}_3, \bar{M}_3, \bar{J}_5$ and $\bar{M}_5)$, (\bar{J}_4, \bar{M}_4) and (\bar{J}_6, \bar{M}_6) , respectively, as shown in Figs. 2b-2e.

Assuming time dependence as $\exp(i\omega t)$, the electric and magnetic fields at an arbitrary point \bar{r}

in region R_1 are [27], [34]:

$$\theta_1(\bar{r})\bar{E}_1(\bar{r}) = \bar{E}^{inc}(\bar{r}) - \int_{S_1} (i\omega\mu_1(\bar{n}_1 \times \bar{H}_1)\Phi_1 - (\bar{n}_1 \times \bar{E}_1) \times \nabla' \Phi_1 - (\bar{n}_1 \cdot \bar{E}_1) \nabla' \Phi_1) ds' \quad (1a)$$

$$\theta_1(\bar{r})\bar{H}_1(\bar{r}) = \bar{H}^{inc}(\bar{r}) + \int_{S_1} (i\omega\epsilon_1(\bar{n}_1 \times \bar{E}_1)\Phi_1 + (\bar{n}_1 \times \bar{H}_1) \times \nabla' \Phi_1 + (\bar{n}_1 \cdot \bar{H}_1) \nabla' \Phi_1) ds' \quad (1b)$$

Similarly, the electric and magnetic fields in region R_2 are:

$$\begin{aligned} \theta_2(\bar{r})\bar{E}_2(\bar{r}) = & - \int_{S_1} (i\omega\mu_2(\bar{n}_2 \times \bar{H}_2)\Phi_2 - (\bar{n}_2 \times \bar{E}_2) \times \nabla' \Phi_2 - (\bar{n}_2 \cdot \bar{E}_2) \nabla' \Phi_2) ds' \\ & - \int_{S_2} (i\omega\mu_2(\bar{n}_3 \times \bar{H}_2)\Phi_2 - (\bar{n}_3 \times \bar{E}_2) \times \nabla' \Phi_2 - (\bar{n}_3 \cdot \bar{E}_2) \nabla' \Phi_2) ds' \\ & - \int_{S_3} (i\omega\mu_2(\bar{n}_5 \times \bar{H}_2)\Phi_2 - (\bar{n}_5 \times \bar{E}_2) \times \nabla' \Phi_2 - (\bar{n}_5 \cdot \bar{E}_2) \nabla' \Phi_2) ds' \end{aligned} \quad (1c)$$

$$\begin{aligned} \theta_2(\bar{r})\bar{H}_2(\bar{r}) = & \int_{S_1} (i\omega\epsilon_2(\bar{n}_2 \times \bar{E}_2)\Phi_2 + (\bar{n}_2 \times \bar{H}_2) \times \nabla' \Phi_2 + (\bar{n}_2 \cdot \bar{H}_2) \nabla' \Phi_2) ds' \\ & + \int_{S_2} (i\omega\epsilon_2(\bar{n}_3 \times \bar{E}_2)\Phi_2 + (\bar{n}_3 \times \bar{H}_2) \times \nabla' \Phi_2 + (\bar{n}_3 \cdot \bar{H}_2) \nabla' \Phi_2) ds' \\ & + \int_{S_3} (i\omega\epsilon_2(\bar{n}_5 \times \bar{E}_2)\Phi_2 + (\bar{n}_5 \times \bar{H}_2) \times \nabla' \Phi_2 + (\bar{n}_5 \cdot \bar{H}_2) \nabla' \Phi_2) ds' \end{aligned} \quad (1d)$$

Similarly, the electric and magnetic fields in region R_3 , are:

$$\theta_3(\bar{r})\bar{E}_3(\bar{r}) = - \int_{S_2} (i\omega\mu_3(\bar{n}_4 \times \bar{H}_3)\Phi_3 - (\bar{n}_4 \times \bar{E}_3) \times \nabla' \Phi_3 - (\bar{n}_4 \cdot \bar{E}_3) \nabla' \Phi_3) ds' \quad (1e)$$

$$\theta_3(\bar{r})\bar{H}_3(\bar{r}) = \int_{S_2} (i\omega\epsilon_3(\bar{n}_4 \times \bar{E}_3)\Phi_3 + (\bar{n}_4 \times \bar{H}_3) \times \nabla' \Phi_3 + (\bar{n}_4 \cdot \bar{H}_3) \nabla' \Phi_3) ds' \quad (1f)$$

Finally, the electric and magnetic fields in region R_4 , are:

$$\theta_4(\bar{r})\bar{E}_4(\bar{r}) = - \int_{S_3} (i\omega\mu_4(\bar{n}_4 \times \bar{H}_4)\Phi_4 - (\bar{n}_4 \times \bar{E}_4) \times \nabla' \Phi_4 - (\bar{n}_4 \cdot \bar{E}_4) \nabla' \Phi_4) ds' \quad (1g)$$

$$\theta_4(\bar{r})\bar{H}_4(\bar{r}) = \int_{S_3} (i\omega\epsilon_4(\bar{n}_6 \times \bar{E}_4)\Phi_4 + (\bar{n}_6 \times \bar{H}_4) \times \nabla' \Phi_4 + (\bar{n}_6 \cdot \bar{H}_4) \nabla' \Phi_4) ds' \quad (1h)$$

The 3-D scalar Green's function is given by $\Phi_i = \exp(-ik_i|\bar{r} - \bar{r}'|)/4\pi|\bar{r} - \bar{r}'|$, where \bar{r} is the field point, \bar{r}' is the source point, and $k_i = \omega\sqrt{\epsilon_i\mu_i}$ is the wave number in each region, $i=1, 2, 3$ and

4. The symbol $\theta_i(\bar{r})$ is the Heaviside function that gives the jump condition at surface S [34].

Applying the boundary conditions for the tangential electric and magnetic field components on surfaces S_1 , S_2 , and S_3 lead to continuity of equivalent surface currents as $(\bar{J}_1 = -\bar{J}_2$ and $\bar{M}_1 = -\bar{M}_2)$, $(\bar{J}_3 = -\bar{J}_4$ and $\bar{M}_3 = -\bar{M}_4)$ and $(\bar{J}_5 = -\bar{J}_6$ and $\bar{M}_5 = -\bar{M}_6)$, respectively.

Equating the tangential component of the electric and magnetic fields on surface S_1 , we get:

$$\bar{E}^{inc}(\bar{r})\big|_{\text{tang.}} = [(L_1 + L_2)\bar{J}_1 - (K_1 + K_2)\bar{M}_1 - L_3\bar{J}_3 + K_3\bar{M}_3 - L_4\bar{J}_5 + K_4\bar{M}_5]_{\text{tang.}} \quad (2)$$

$$\bar{H}^{inc}(\bar{r})\big|_{\text{tang.}} = \left[(K_1 + K_2)\bar{J}_1 + \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{M}_1 - K_3\bar{J}_3 - \frac{L_3}{\eta_2^2} \bar{M}_3 - K_4\bar{J}_5 - \frac{L_4}{\eta_2^2} \bar{M}_5 \right]_{\text{tang.}} \quad (3)$$

on surface S_2

$$0 = [-L_2\bar{J}_1 + K_2\bar{M}_1 + (L_3 + L_5)\bar{J}_3 - (K_3 + K_5)\bar{M}_3 + L_4\bar{J}_5 - K_4\bar{M}_5]_{\text{tang.}} \quad (4)$$

$$0 = \left[-K_2\bar{J}_1 - \frac{L_2}{\eta_2^2} \bar{M}_1 + (K_3 + K_5)\bar{J}_3 + \left(\frac{L_3}{\eta_2^2} + \frac{L_5}{\eta_3^2} \right) \bar{M}_3 + K_4\bar{J}_5 + \frac{L_4}{\eta_2^2} \bar{M}_5 \right]_{\text{tang.}} \quad (5)$$

on surface S_3

$$0 = \left[-L_2 \bar{J}_1 + K_2 \bar{M}_1 + L_3 \bar{J}_3 - K_3 \bar{M}_3 + (L_4 + L_6) \bar{J}_5 - (K_4 + K_6) \bar{M}_5 \right]_{\text{tang.}} \quad (6)$$

$$0 = \left[-K_2 \bar{J}_1 + \frac{L_2}{\eta_2^2} \bar{M}_1 + K_3 \bar{J}_3 + \frac{L_3}{\eta_2^2} \bar{M}_3 + (K_4 + K_6) \bar{J}_5 + \left(\frac{L_4}{\eta_2^2} + \frac{L_6}{\eta_4^2} \right) \bar{M}_5 \right]_{\text{tang.}} \quad (7)$$

in which the intrinsic impedance is $\eta_i = \sqrt{\mu_i / \epsilon_i}$, in region R_i with $i = 1, 2, \dots, 4$ and L_j and K_j , $j = 1, 2, \dots, 6$ are the integro-differential operators as given in Appendix A. The surfaces S_1, S_2 and S_3 are discretized into triangular patches where the unknown equivalent electric and magnetic currents in Eqs. 2-7 are approximated by using the RWG vector basis functions $\bar{j}(\bar{r})$ [35] as:

$$\bar{J}_i(\bar{r}) = \sum_{n=1}^{N_k} I_{in} \bar{j}_{kn}(\bar{r}), \quad \bar{M}_i(\bar{r}) = \eta_i \sum_{n=1}^{N_k} I_{(i+1)n} \bar{j}_{kn}(\bar{r}), \quad \bar{r} \in S_k, \quad \text{for } i = 1, 3 \text{ and } 5 \quad (8)$$

in which $k = 1$ for $i = 1$, $k = 2$ for $i = 3$ and $k = 3$ for $i = 5$. Upon substituting Eq. 8 into Eq. 2-7, normalizing the H -field equations by η_1 , and applying Galerkin's method for testing the E - and H -field equations, the linear system of equations is obtained:

$$\bar{\bar{Z}} \bar{I} = \bar{V} \Rightarrow \begin{pmatrix} \bar{Z}_{11} & \bar{Z}_{12} & \bar{Z}_{13} \\ \bar{Z}_{21} & \bar{Z}_{22} & \bar{Z}_{23} \\ \bar{Z}_{31} & \bar{Z}_{32} & \bar{Z}_{33} \end{pmatrix} \begin{pmatrix} I^1 \\ I^2 \\ I^3 \end{pmatrix} = \begin{pmatrix} \bar{V}_1 \\ 0 \\ 0 \end{pmatrix} \quad (9)$$

The submatrix \bar{Z}_{11} has order of $2N_1 \times 2N_1$ and represents interactions between elements only on surface S_1 , the submatrix \bar{Z}_{22} has order of $2N_2 \times 2N_2$ and represents interactions between elements only on surface S_2 , and the submatrix \bar{Z}_{33} has order of $2N_3 \times 2N_3$ and represents interactions between elements only on surface S_3 . The other submatrices in Eq. 9 represent interactions between different surfaces, e.g., \bar{Z}_{12} represents interactions between elements on surface S_1 and elements on surface S_2 , etc. The details of these submatrices are given in

Appendix B. This implies that the total matrix $\bar{\bar{Z}}$ has order of $2(N_1 + N_2 + N_3) \times 2(N_1 + N_2 + N_3)$ and it accounts for all interactions between different surfaces. The tested tangential incident electric field \bar{E}^{inc} and the tested normalized magnetic field $\eta_1 \bar{H}^{inc}$ on the exterior surface S_1 are represented by vector \bar{V}_1 . Solving the system of equations in Eq. 9 by using the MoM (Method of Moments) requires computing and storing the full dense matrix $\bar{\bar{Z}}$ and then multiplying it by the vector \bar{V} , which leads to a very computational expensive process. Therefore, the SDFMM is used to solve Eq. 9 leading to reduce the computational complexity for the CPU time and the computer memory to be only of $O(K)$ per iteration instead of $O(K^2)$ using the MoM [30]-[33], where $K = 2(N_1 + N_2 + N_3)$ is the total number of the current unknowns.

I. NUMERICAL RESULTS

In all results, the incident wave is assumed to be a Gaussian beam [36] that is carefully tapered to eliminate the effects of the artificial edges of the ground surface that has dimensions of $8\lambda_0 \times 8\lambda_0$ [27]. The half beam width of the Gaussian beam is assumed to be $1.6\lambda_0$ which illuminates the ground with plane waves over a spot of diameter $3.2\lambda_0$ centered at $x = 4\lambda_0, y = 4\lambda_0$ (same as ground center). The beam is incident normally towards the ground, with either horizontal or vertical polarization, i.e. the incident electric field will be in the y -direction or in the x -direction, respectively, see Fig. 1. Point receivers are located at height $0.5\lambda_0$ above the mean ground with resolution equal to $0.04\lambda_0$. The rough ground characterized with Gaussian random heights and Gaussian autocorrelation function such that the roughness will be described by the standard deviation of the height σ and the correlation length l_c , with assuming

zero mean height. The relative dielectric constant of the ground is assumed to be $\epsilon_r = 2.5 - j0.18$ [37] while the dielectric constant of each object will be stated for each in this section. The used discretization distance on the ground surface is $0.08\lambda_0$ leading to 60,000 electric and magnetic surface current unknowns, while using almost the same discretization rate for the two objects generates approximately 600 unknowns for each one.

In this section, images for the two penetrable objects that are buried under the ground will be presented. These images are based on the magnitude of the scattered electric fields which are received in the near zone above the ground [38], see Fig. 1. In Figs. 3 and 4, the ground is assumed to be flat in order to demonstrate the clutter due only to the second object (without the clutter due to presence of the rough ground). The scattered fields due to just the two objects are obtained by subtracting the ground returns from the total scattered fields in complex vector representation. Excellent agreement between the results of the SDFMM and those of the MoM is obtained which is used to validate the current computer code. Our parametric investigation includes studying the effect on the scattered fields due to proximity between the two objects, their materials, shapes and orientations, incidence polarization and ground roughness. The images shown in Figs. 3a-c are for two oblate spheroids both have dimensions $a = 0.15\lambda_0, b = 0.3\lambda_0$, material of $\epsilon_r = 2.9 - j0.072$ and buried at $z = -0.3\lambda_0$. They are located diagonally at $x = 4.5\lambda_0, y = 3.5\lambda_0$ and $x = 3.5\lambda_0, y = 4.5\lambda_0$ in Fig. 3a, at $x = 5\lambda_0, y = 3\lambda_0$ and $x = 3\lambda_0, y = 5\lambda_0$ in Fig. 3b, and at $x = 5.5\lambda_0, y = 2.5\lambda_0$ and $x = 2.5\lambda_0, y = 5.5\lambda_0$ in Fig. 3c. This implies that the separation distance from the center of the first object to the center of the second object is $D_x = D_y = 1\lambda_0, 2\lambda_0$, and $3\lambda_0$ in Fig. 3a, 3b and 3c, respectively, where D_x and D_y are the distance in the x - and y -direction. A significant interference between the two objects is observed in Fig. 3a where the separation distance is equal to one free space wavelength

($D_x = D_y = 1\lambda_0$). This coupling between the two objects decreases with the increase of the separation distance as shown in Fig. 3b and 3c. This implies that if these two objects are separated by three wavelengths of free space or more, then each object can be detected separately from the other one, e.g. by narrowing the width of the incident beam. Moreover, the results in Figs. 3a-c show the degradation of the signature of both objects as their positions are moved away from the center of the ground where the incident beam is centered, which agrees with our finding in [28].

Next, we change the shape of the objects, which consequently affects the scattered electric fields as shown in Figs. 4a-c. In these figures, the shape of one object is assumed to be the same spheroid as used in Fig. 3 while the second object is changed to be a sphere of radius $a = 0.15\lambda_0$ in Fig. 4a, an ellipsoid of dimensions $a = 0.15\lambda_0, b = 0.3\lambda_0, c = 0.15\lambda_0$ in Fig. 4b and a vertical cylinder of radius $a = 0.15\lambda_0$ and height $h = 0.15\lambda_0$ in Fig. 4c. The two objects in Fig. 4a-c are located similar to those in Fig. 3a where the separation distance between them (from center to center) is also $D_x = D_y = 1\lambda_0$. The scattered fields from just both the spheroid and the sphere, both the spheroid and the ellipsoid and both the spheroid and the cylinder are shown in Fig. 4a, 4b and 4c, respectively. The results show that the signature of the spheroid (located in the upper left quadrant) is much larger than the signature of the sphere, ellipsoid or the vertical cylinder (located in the lower right quadrant). However, the signature of the spheroid with the presence of the ellipsoid has slightly larger value than it with the presence of either the sphere or the vertical cylinder. Moreover, because the two objects have different shapes and sizes, the interference between them is clearly not symmetric, contrary to the results of Figs. 3a-c. In Fig. 3 and 4, the two objects are assumed to have the same material ($\epsilon_r = 2.9 - j0.072$) and they are buried under a flat ground. To simulate a more realistic case, different material for the second object will be

assumed with also incorporating the ground roughness in the model. In this case, the spheroid is assumed to have the same material and dimensions as in Fig. 3 and it will be located at $x = 4.5\lambda_0$, $y = 3.5\lambda_0$ and $z = -0.3\lambda_0$ (lower right quadrant). The second object is assumed to be a horizontal cylinder of radius $a = 0.15\lambda_0$, height $h = 0.9\lambda_0$ with its axis tilted at angle 30° with the x -direction (see Fig. 1). The material of this horizontal cylinder is assumed to be lossless with $\epsilon_r = 4$ and its center is located at $x = 4.01\lambda_0$, $y = 4.375\lambda_0$ and $z = -0.3\lambda_0$ (upper right quadrant) which implies that the separation distance will be $D_x = 0.49\lambda_0$ and $D_y = 0.875\lambda_0$. The rms height of the random rough ground is assumed to be $\sigma = 0.04\lambda_0$ with the correlation length of $l_c = 0.5\lambda_0$. The results in Fig. 5a and 5b are for the incident H- and V-polarization, respectively. These results show that the signature of the horizontal cylinder (upper left quadrant) is dominating the image with maximum amplitude of almost three times larger than that of the spheroid (lower right quadrant). This is due to the larger size and dielectric constant of the cylinder than those of the spheroid. Moreover, the tilted position of the horizontal cylinder could have contributed to this observation as well. Polarization dependency of the scattered electric fields is clearly observed upon comparing Fig. 5a (horizontal polarization) with Fig. 5b (vertical polarization), with slight increase in the maximum amplitude in the later case. Moreover, the results in Figs. 5a and 5b indicate that the presence of the cylinder (clutter item) can easily cause a false alarm in detecting the spheroid (target) in both polarizations. In order to analyze the image of the spheroid alone, all sources of clutter should be removed, i.e. removing the return from both the cylinder and the rough ground. The output, for incident H-polarization, is presented in Fig. 5c where a clear image of just the spheroid is shown. Similar results for the case of incident V-polarization is observed. Then, for the incident H-polarization, the roughness

of the ground is increased to be $\sigma = 0.1\lambda_0$ with the same correlation length as before where the image of the just spheroid is shown in Fig. 5d. All data in Fig. 5d are the same as in Fig. 5a except that the burial depth is increased to be $z = -0.4\lambda_0$ in this case. Comparing Fig. 5d with Fig. 5c, it is clear that increasing the ground roughness has increased the distortion in the image. The decrease in the amplitude in Fig. 5d compared with that in Fig. 5c could mainly be due to the larger burial depth of the spheroid in the later case that causes more attenuation in the transmitting waves. The same spheroid and cylinder used in Figs. 5a are buried under a flat ground instead of the rough ground as shown in Fig. 6a where the image of the spheroid alone is obtained also by removing the return from both the cylinder and the flat ground. Moreover, the same spheroid used in Fig. 5a is buried as a single object (no nearby buried cylinder) under the flat ground as shown in Fig. 6b where the image of the spheroid alone is obtained. Comparing Fig. 6a with Fig. 6b show the distortion due to only the presence of the nearby cylinder, while comparing Fig. 5c and 5d with Fig. 6a show the distortion due to the ground roughness. However, comparing Fig. 5c and 5d with Fig. 6b show the distortion due to the presence of both the rough ground and the nearby cylinder. Moreover, the image in Fig. 5c is slightly different from that in Fig. 6a due to the small roughness in this case but the image in Fig. 5d is more distorted due to the increase in ground roughness. In all previous results, the clutters are removed by subtraction using complex vector representation, but when the subtraction is processed using only the magnitude of the fields (i.e. ignoring the phase), the images of the spheroid looked more distorted as the ground roughness increases.

In all results, the SDFMM code required 850MB computer memory, 25 CPU minutes to fill the near field matrix, 23 CPU minutes to calculate the near scattered fields with $0.04\lambda_0$, and 4.6 CPU hours to obtain relative error equal to 10^{-5} for the TFQMR iterative solver.

CONCLUSIONS

In this work, we analyzed the 3-D scattering problem of the two dielectric shallow objects buried under the two-dimensional random rough ground. The fast algorithm, SDFMM, is used to solve the obtained linear system of equations for the electric and magnetic surface current unknown coefficients. Our parametric investigation results show the significant effect of the separation distance between the two objects and the ground roughness on the target signature. The numerical results show clear distortion due to the ground roughness and, more interestingly, they show the possible false alarm in detecting the target due to the presence of the second object (clutter item). The SDFMM has efficiently made the current 3-D computations tractable in an accurate and fast manner.

ACKNOWLEDGEMENTS

This research was sponsored from the Northeastern University's Demining MURI grant # DAA 0-55-97-0013 and in part by the College of Engineering at the University of Arkansas. The author would like to thank Prof. W. Chew, Prof. E. Michielssen at UIUC for allowing the use and modification of the SDFMM computer code for the current application. This work benefited from the allocation of time at the Northeastern University Advanced Scientific Computation Center (NU-ASCC).

Appendix A

With representing the surface electric and magnetic currents \bar{J} and \bar{M} on S_1 , S_2 and S_3 by the vector \bar{X} , the integro-differential operators L_j and $K_j, j=1, 2, \dots, 6$, are [27], [34]:

$$L_{1,2}\bar{X} = \int_{S_1} \left\{ i\omega\mu_{1,2}\Phi_{1,2}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{1,2}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{1,2} \right\} ds', \quad K_{1,2}\bar{X} = \int_{S_1} \bar{X}(\bar{r}') \times \nabla\Phi_{1,2} ds' \quad (A1)$$

$$L_{3,5}\bar{X} = \int_{S_2} \left\{ i\omega\mu_{2,3}\Phi_{2,3}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{2,3}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{2,3} \right\} ds', \quad K_{3,5}\bar{X} = \int_{S_2} \bar{X}(\bar{r}') \times \nabla\Phi_{2,3} ds' \quad (A2)$$

$$L_{4,6}\bar{X} = \int_{S_3} \left\{ i\omega\mu_{2,4}\Phi_{2,4}\bar{X}(\bar{r}') + \frac{i}{\omega\epsilon_{2,4}}\nabla\nabla' \cdot \bar{X}(\bar{r}')\Phi_{2,4} \right\} ds', \quad K_{4,6}\bar{X} = \int_{S_3} \bar{X}(\bar{r}') \times \nabla\Phi_{2,4} ds' \quad (A3)$$

Appendix B

The elements of the submatrix \bar{Z}_{11} in (9) are given by

$$\bar{Z}_{11} = \begin{pmatrix} \langle \bar{j}_1, (L_1 + L_2)\bar{j}_1 \rangle_{S_1} & \langle \bar{j}_1, -\eta_1(K_1 + K_2)\bar{j}_1 \rangle_{S_1} \\ \langle \bar{j}_1, \eta_1(K_1 + K_2)\bar{j}_1 \rangle_{S_1} & \left\langle \bar{j}_1, \eta_1^2 \left(\frac{L_1}{\eta_1^2} + \frac{L_2}{\eta_2^2} \right) \bar{j}_1 \right\rangle_{S_1} \end{pmatrix} \quad (B1)$$

in which $\langle \bar{A}, \bar{B} \rangle_S$ denotes the complex inner product between vector functions \bar{A} and \bar{B} on a

surface S [27], [34]. Similarly, the elements of the submatrices \bar{Z}_{22} and \bar{Z}_{33} are given by

$$\bar{Z}_{22} = \begin{pmatrix} \langle \bar{j}_2, (L_3 + L_5)\bar{j}_2 \rangle_{S_2} & \langle \bar{j}_2, -\eta_1(K_3 + K_5)\bar{j}_2 \rangle_{S_2} \\ \langle \bar{j}_2, \eta_1(K_3 + K_5)\bar{j}_2 \rangle_{S_2} & \left\langle \bar{j}_2, \eta_1^2 \left(\frac{L_3}{\eta_2^2} + \frac{L_5}{\eta_3^2} \right) \bar{j}_2 \right\rangle_{S_2} \end{pmatrix} \quad (B2)$$

$$\bar{Z}_{33} = \begin{pmatrix} \langle \bar{j}_3, (L_4 + L_6)\bar{j}_3 \rangle_{S_3} & \langle \bar{j}_3, -\eta_1(K_4 + K_6)\bar{j}_3 \rangle_{S_3} \\ \langle \bar{j}_3, \eta_1(K_4 + K_6)\bar{j}_3 \rangle_{S_3} & \left\langle \bar{j}_3, \eta_1^2 \left(\frac{L_4}{\eta_2^2} + \frac{L_6}{\eta_4^2} \right) \bar{j}_3 \right\rangle_{S_3} \end{pmatrix} \quad (B3)$$

While submatrices \bar{Z}_{12} , \bar{Z}_{13} , \bar{Z}_{21} , \bar{Z}_{31} , \bar{Z}_{23} and \bar{Z}_{32} are given by

$$\bar{Z}_{12} = \begin{pmatrix} \langle \bar{j}_1, -L_3 \bar{j}_2 \rangle_{s_1} & \langle \bar{j}_1, \eta_1 K_3 \bar{j}_2 \rangle_{s_1} \\ \langle \bar{j}_1, -\eta_1 K_3 \bar{j}_2 \rangle_{s_1} & \left\langle \bar{j}_1, -\eta_1^2 \left(\frac{L_3}{\eta_2^2} \right) \bar{j}_2 \right\rangle_{s_1} \end{pmatrix} \quad (\text{B4})$$

$$\bar{Z}_{21} = \begin{pmatrix} \langle \bar{j}_2, -L_2 \bar{j}_1 \rangle_{s_2} & \langle \bar{j}_2, \eta_1 K_2 \bar{j}_1 \rangle_{s_2} \\ \langle \bar{j}_2, -\eta_1 K_2 \bar{j}_1 \rangle_{s_2} & \left\langle \bar{j}_2, -\eta_1^2 \left(\frac{L_2}{\eta_2^2} \right) \bar{j}_1 \right\rangle_{s_2} \end{pmatrix} \quad (\text{B5})$$

$$\bar{Z}_{13} = \begin{pmatrix} \langle \bar{j}_1, -L_4 \bar{j}_3 \rangle_{s_1} & \langle \bar{j}_1, \eta_1 K_4 \bar{j}_3 \rangle_{s_1} \\ \langle \bar{j}_1, -\eta_1 K_4 \bar{j}_3 \rangle_{s_1} & \left\langle \bar{j}_1, -\eta_1^2 \left(\frac{L_4}{\eta_2^2} \right) \bar{j}_3 \right\rangle_{s_1} \end{pmatrix} \quad (\text{B6})$$

$$\bar{Z}_{31} = \begin{pmatrix} \langle \bar{j}_3, -L_2 \bar{j}_1 \rangle_{s_3} & \langle \bar{j}_3, \eta_1 K_2 \bar{j}_1 \rangle_{s_3} \\ \langle \bar{j}_3, -\eta_1 K_2 \bar{j}_1 \rangle_{s_3} & \left\langle \bar{j}_3, -\eta_1^2 \left(\frac{L_2}{\eta_2^2} \right) \bar{j}_1 \right\rangle_{s_3} \end{pmatrix} \quad (\text{B7})$$

$$\bar{Z}_{23} = \begin{pmatrix} \langle \bar{j}_2, L_4 \bar{j}_3 \rangle_{s_2} & \langle \bar{j}_2, -\eta_1 K_4 \bar{j}_3 \rangle_{s_2} \\ \langle \bar{j}_2, \eta_1 K_4 \bar{j}_3 \rangle_{s_2} & \left\langle \bar{j}_2, \eta_1^2 \frac{L_4}{\eta_2^2} \bar{j}_3 \right\rangle_{s_2} \end{pmatrix} \quad (\text{B8})$$

$$\bar{Z}_{32} = \begin{pmatrix} \langle \bar{j}_3, L_3 \bar{j}_2 \rangle_{s_3} & \langle \bar{j}_3, -\eta_1 K_3 \bar{j}_2 \rangle_{s_3} \\ \langle \bar{j}_3, \eta_1 K_3 \bar{j}_2 \rangle_{s_3} & \left\langle \bar{j}_3, \eta_1^2 \frac{L_3}{\eta_2^2} \bar{j}_2 \right\rangle_{s_3} \end{pmatrix} \quad (\text{B9})$$

in which there are nice symmetrical relationships that leads to computing and storing elements of only eighteen out of the thirty six submatrices to gain significant reduction in CPU time and computer memory requirements for the dense matrix $\bar{\bar{Z}}$ [27].

The scattering of electromagnetic waves from a penetrable shallow target buried beneath 2-D multilayered random rough surfaces will be presented. There are several applications for this work, e.g. detection of anti-personnel mines, anti-tank mines, water and/or gas pipes, location of underground water, etc. In reality, these targets are buried under the Earth's surface, which is a randomly rough interface and also is not simply composed of a single layer, but is a multilayered media. The closer the real environment is incorporated into the electromagnetic model, the more accurate and practical inferences can be gained from the numerical results. Without modeling the multiple ground layers, many targets *cannot be detected*. One unobtrusive way these buried targets can be detected is by bombarding the Earth's surface with electromagnetic waves, and comparing the scattered signature of the ground alone with that of the ground with the buried target.

A rigorous electromagnetic model based on the equivalence theorem and the method of moments (MoM) is developed to analyze this 3-D scattering problem. Three layers are considered in this work; air, dry-soil and wet-soil. The penetrable target is buried between the air/dry-soil interface and the dry/wet-soil interface. The Steepest Descent Fast Multipole Method (SDFMM) is implemented to significantly accelerate the computations of the unknown electric and magnetic surface currents. The effect of the lossy underground rough layer (wet soil) on the target signature will be investigated. Moreover, images based on the scattered electric fields for the buried target will be presented.

Invited paper.

A rigorous electromagnetic model has been developed to analyze the scattering mechanism of a target buried near a clutter-object under the two-dimensional random rough ground (3-D scattering problem). In realistic landmine fields, the anti-personnel (AP) nonmetallic mine is often buried nearby a rock, tree root, etc. The presence of a second object buried near the nonmetallic mine can easily obscure the target and/or cause a false alarm during the detection process.

The rigorous model is based on the classical electromagnetic equivalence theorem leading to producing six new integral equations. Using the Method of Moment (MoM), the new integral equations are transformed into a linear system of equations to be solved for the unknown electric and magnetic currents on the surface of three scatterers; rough ground, target and clutter-object. The MoM impedance matrix completely represents every interaction between these three scatterers. The Steepest Descent Fast Multipole Method (SDFMM) is used to tremendously accelerate the computations of the unknown MoM surface currents.

In previous work, we thoroughly investigated the effect of ground roughness on the signature of the target when it is buried alone under the ground. In this work, we will present numerical results for parametric investigations of the objects proximity, orientations, materials, and shapes. The results show that in certain situations, the target can be completely obscured due to the presence of the nearby clutter-object (e.g., tree root). In other cases a false indication of presence of a third buried object is observed. When the sources of clutter (e.g. the rough ground and the clutter object) are removed, by subtracting the return from both the rough ground and the clutter-object, the signature of the target can be clearly observed and analyzed. The numerical results show that the ground roughness along with the separation distance, between the target and the clutter-object, play a significant role on the probability of true or false alarm in the detection process.

The multiple interaction approach is used with the robust Steepest Descent Fast Multipole Method (SDFMM) to compute the signature of non-shallow penetrable scatterers buried beneath 2-D random rough surfaces. The most attractive feature of the proposed model is removing the quasi-planar structure constraint of the Steepest Descent Fast Multipole Method (SDFMM) when used in analyzing non-quasi-planar scatterers. The basic idea of the multiple interaction model is to decompose certain non-quasi-planar structures into two quasi-planar scatterers where the conventional SDFMM can be applied separately to each one. The interactions between the sub-quasi-planar scatterers are calculated directly using the electromagnetic vector potentials near-field expressions. Significant reductions in the CPU time and computer memory are achieved by using the SDFMM in the model. A variety of geometries are used to test the model and their numerical results are validated with the conventional MoM.

The results show that the buried object's signature is largely due to the first interaction mechanism (i.e. ground-object-ground). However, the contribution of each additional interaction is explicitly calculated using the model. Interestingly, the contributions from repeating this mechanism become insignificant especially for lossy background soil. This conclusion depends on the physical properties of the scatterer.

The multiple interaction model successfully demonstrates the exploitation of the SDFMM robustness when applied to the multilayered rough ground where the burial depth of the underground rough layer is on the order of a wavelength.

Abstract

Scattering of electromagnetic waves from multilayered random rough surfaces is crucial for subsurface sensing applications. A multiple interaction method of moments (MoM) model is used in this work to analyze scattering from two-dimensional multilayered random rough ground (3-D scattering problem) especially when the underground layer is deeply buried under the air/ground interface. The presented model removes a barrier and enables the application of the Steepest Descent Fast Multipole Method (SDFMM) to certain 3-D non-quasi-planar structures. The conventional SDFMM has been used to analyze electromagnetic wave scattering from quasi-planar structures where the scatterer's height is a fraction of a free-space wavelength. The presented model is based on a multiple interactions mechanism between the rough air/ground interface and the underground rough layer. The basic idea of the proposed model is to decompose the non-quasi-planar multilayered structure into two quasi-planar scatterers where the conventional SDFMM can be applied separately to each one. The interactions between the sub-quasi-planar scatterers are calculated using the electromagnetic vector potentials near-field expressions. This model is tested and validated with the MoM on a variety of geometries. The results show that the strongest signature of the buried scatterer is mainly due to the first multiple interaction mechanism (ground-object-ground) while the contributions from repeating this mechanism become insignificant even for lossless and/or slightly lossy soil.

Parametric Investigation of Ground Roughness on the Interference Between the AP-Mine and a Clutter-Object Buried Under Two-Dimensional Random Rough Surfaces

In realistic landmine fields, the anti-personnel plastic mine is often buried nearby a clutter-object under the ground. The presence of a second object buried near the mine under a two-dimensional (2-D) rough ground can easily obscure the target and/or cause a false alarm. The separation distance between the AP mine and clutter-object plays a significant role on the probability of true or false alarm in this situation. A rigorous electromagnetic model has been developed to analyze the scattering mechanism between the target and the clutter-object, between the target and the rough ground, between the clutter-object and the rough ground and the multiple scattering between different spots on the rough ground itself. The new rigorous model is based on the classical electromagnetic equivalence theorem leading to producing six new integral equations. Using the Method of Moment (MoM), the new integral equations are transformed into a linear system of equations to be solved for the unknown electric and magnetic currents on the surface of three scatterers; (1) rough ground, (2) target and (3) clutter-object. The MoM impedance matrix completely represents every interaction between these three scatterers. The superior Steepest Descent Fast Multipole Method (SDFMM) is used to tremendously speed up the computations of the unknown MoM surface currents.

In previous work, we thoroughly investigated the significant effect of ground roughness on the signature of the target buried alone under the ground. Recently, we conducted a generalized parametric investigation on the objects proximity, orientations, materials, and shapes. In certain situations, the target is completely obscured due to the presence of the nearby clutter-object (e.g., tree root), and in other cases a false indication of the presence of a third buried object is observed. However, when all considered sources of clutter; (1) rough ground and (2) clutter object, are removed, by removing the return from both the rough ground and the clutter-object, the signature of the target can be clearly observed and analyzed.

In this work we will emphasize on investigating the association between the ground roughness parameters and the separation distance between the two objects and its influence on the possibility of false alarms.

Double-scatter cross sections for two-dimensional random rough surfaces that exhibit backscatter enhancement

Full-wave solutions are given for the single- and double-scatter radar cross sections for two-dimensional random rough surfaces. High-frequency approximations are used for the double-scatter cross sections in order to express them as numerically tractable four-dimensional integrals. The major contributions to the double-scatter cross sections are associated with the quasi-parallel and quasi-antiparallel double-scatter paths. They come from the neighborhoods of specular points. The enhancement of the backscatter cross sections, which is associated with the quasi-antiparallel double-scatter paths, is observed for both the like- and cross-polarized cross sections. © 2001 Optical Society of America

1. INTRODUCTION

In this work, full-wave solutions for the single- and double-scatter radar cross sections for two-dimensional random rough surfaces are given. The solutions are expressed as multidimensional integrals. The high-frequency, physical optics approximations are used to reduce 12-dimensional integral expressions for the double-scatter cross sections, and the large-radius-of-curvature approximation is used. The associated single-scatter cross sections are expressed in closed form. The incident waves are assumed to be plane waves.

Similar to the case for scattering from one-dimensional random rough surfaces,¹ the major contributions to the double-scatter cross sections are associated with two different pairs of propagation paths. They are the quasi-parallel double-scatter paths and the quasi-antiparallel double-scatter paths. The total incoherent double-scatter cross section is the sum of the incoherent quasi-parallel and quasi-antiparallel double-scatter cross sections.

In the high-frequency limit, the major contributions to the single- and double-scatter cross sections come from the neighborhoods of the specular points on the rough surface. Thus, upon integration with respect to the random-rough-surface slopes, the surface element scattering coefficients are evaluated at the specular points. The probability density functions for the slopes and the heights are assumed to be Gaussian. Shadow functions are included in the analysis. Physical interpretations of the analytical results are provided here.

The effects of changing the rough-surface parameters [such as mean square height and mean square slope (mss)] on the double-scatter cross sections are studied.

The level and the width of the enhancement in the backscatter direction depend on the mean square height and slope of the rough surface. The sharp backscatter enhancement, which is observed for both the like- and cross-polarized cross sections and for both normal and oblique incident angles, is associated with the quasi-antiparallel double-scatter paths. The medium below the rough interface is characterized by a complex dielectric coefficient. This work is an extension of earlier work that is restricted to scattering in the incident plane by one-dimensional rough surfaces.¹ Thus depolarization is not considered in the earlier work. It is relevant to work in remote sensing and to the design of targets with unusually large backscatter cross sections, such as traffic signs and decoys (reversed stealth).

2. FORMULATION OF THE PROBLEM

The full-wave solutions for the double-scatter electromagnetic far fields $G_d^f(\bar{r})$ from two-dimensional rough surfaces [$y = h(x_s, z_s)$] are given by¹

$$G_d^f(\bar{r}) = \left(\frac{k_0}{2\pi j} \right)^3 \frac{\exp(-jk_0 r)}{r} \int \frac{D_{2'}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i)}{n_y^f - n_y^i} \times \exp(jk_0 \hat{\mathbf{n}}^f \cdot \mathbf{r}_{s2'}) \times \exp[-jk_0 \hat{\mathbf{n}}^i \cdot (\mathbf{r}_{s2'} - \mathbf{r}_{s1'})] \frac{D_{1'}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i)}{-n_y^i + n_y^f} \times \exp(-jk_0 \hat{\mathbf{n}}^i \cdot \mathbf{r}_{s1'}) \frac{dn_y' dn_z'}{(1 - n_y'^2 - n_z'^2)^{1/2}} \times U(\mathbf{r}_{s1'}) U(\mathbf{r}_{s2'}) dx_{s1'} dz_{s1'} dx_{s2'} dz_{s2'} G^i(0), \quad (1)$$

in which the time-harmonic excitations $\exp(j\omega t)$ are assumed and the free-space wave number is $k_0 = \omega \sqrt{\epsilon_0 \mu_0}$. The integration in Eq. (1) is over the radar footprint $A = 4l_x l_z$ and components of \hat{n}' . The incident waves are in the direction of the unit vector \hat{n}^i , and the scattered waves are in the direction of the unit vector \hat{n}^f from the rough surface to the receiver at \mathbf{r} . Thus, in terms of the Cartesian unit vectors \hat{e}_i ($i = x, y, z$),

$$\hat{n}^i = n_x^i \hat{e}_x + n_y^i \hat{e}_y + n_z^i \hat{e}_z, \quad (2a)$$

$$\hat{n}^f = n_x^f \hat{e}_x + n_y^f \hat{e}_y + n_z^f \hat{e}_z, \quad (2b)$$

$$\mathbf{r} = x \hat{e}_x + y \hat{e}_y + z \hat{e}_z, \quad (2c)$$

$$\hat{n}' = n_x' \hat{e}_x + n_y' \hat{e}_y + n_z' \hat{e}_z. \quad (2d)$$

The scattering matrices at points 1' and 2' on the rough surface are $D_{1'}(\hat{n}', \hat{n}^i)$ and $D_{2'}(\hat{n}', \hat{n}^i)$ [see Fig. 1(a)]. The elements of the scattering matrices depend on the local slope of the rough surface.^{1,2} Moreover, they depend on the polarization of the incident and scattered waves and the media on both sides of the rough interface. The incident fields are assumed to be plane waves, and the receiver is located in the far field. The wave vectors of the scattered waves from the point 1' on the surface are in the direction of the unit vector \hat{n}' [see Fig. 1(a)]. The position vectors to points 1' and 2' on the rough surface are given by

$$\mathbf{r}_{s1'} = x_{s1'} \hat{e}_x + h(x_{s1'}, z_{s1'}) \hat{e}_y + z_{s1'} \hat{e}_z, \quad (3a)$$

$$\mathbf{r}_{s2'} = x_{s2'} \hat{e}_x + h(x_{s2'}, z_{s2'}) \hat{e}_y + z_{s2'} \hat{e}_z. \quad (3b)$$

At high frequencies, the shadow function $U(\mathbf{r}_{s1'})$ is equal to unity if point 1' is illuminated by the incident plane wave and visible at point 2', and it is zero otherwise; and $U(\mathbf{r}_{s2'})$ is equal to unity if point 2' is illuminated by a point source at 1' and visible from the receiver,³ and it is zero otherwise. The double-scatter cross section is obtained on multiplying Eq. (1) by its complex conjugate [see Fig. 1(b)]. The radar cross section for the two-dimensional rough surface is defined as

$$\sigma_T = \frac{4\pi r^2}{A} \left| \frac{G^f}{G^i} \right|^2, \quad (4)$$

$$\begin{aligned} \sigma_T = & \frac{k_0^6}{16A\pi^5} \\ & \times \int \frac{D_{2'}(\hat{n}', \hat{n}^i) D_{1'}(\hat{n}', \hat{n}^i) D_{2'}^*(\hat{n}', \hat{n}^i) D_{1'}^*(\hat{n}', \hat{n}^i)}{(n_y^f - n_y')(n_y^f - n_y'')(n_y^i + n_y')(n_y^i + n_y'')} \\ & \times U(\mathbf{r}_{s1'}) U(\mathbf{r}_{s1'')^*} U(\mathbf{r}_{s2'}) U(\mathbf{r}_{s2'')^*} \\ & \times \exp\{jk_0[n_x^f(x_{s2'} - x_{s2'') + n_y^f(h_{2'} - h_{2'')}) \\ & + n_z^f(z_{s2'} - z_{s2'')]\} \exp\{-jk_0[n_x^i(x_{s2'} - x_{s1'}) \\ & + n_y^i(h_{2'} - h_{1'}) + n_z^i(z_{s2'} - z_{s1'})]\} \\ & \times \exp\{jk_0[n_x''(x_{s2''} - x_{s1'') + n_y''(h_{2''} - h_{1'')}) \\ & + n_z''(z_{s2''} - z_{s1'')]\} \exp\{-jk_0[n_x^i(x_{s1'} - x_{s1'') \\ & + n_y^i(h_{1'} - h_{1'') + n_z^i(z_{s1'} - z_{s1'')]\} \\ & \times \frac{dn_y' dn_z'}{(1 - n_y'^2 - n_z'^2)^{1/2}} \frac{dn_y'' dn_z''}{(1 - n_y''^2 - n_z''^2)^{1/2}} \\ & \times dx_{s1'} dz_{s1'} dx_{s2'} dz_{s2'} dx_{s1''} dz_{s1''} dx_{s2''} dz_{s2''}. \end{aligned} \quad (5)$$

In Eq. (5) the superscript * denotes the complex conjugate. For the quasi-parallel double-scatter paths, between points 1' and 2' and points 1'' and 2'' [see Fig. 1(c)] ($n_\alpha', n_\alpha'' < 0$ and $n_\alpha', n_\alpha'' > 0$; $\alpha = x, z$), the following transformations of variables are used:

$$x_{d1} = x_{s1'} - x_{s1''}, \quad x_{d2} = x_{s2'} - x_{s2''}, \quad (6a)$$

$$z_{d1} = z_{s1'} - z_{s1''}, \quad z_{d2} = z_{s2'} - z_{s2''}, \quad (6b)$$

$$x_{a1} = (x_{s1'} + x_{s1'')/2, \quad x_{a2} = (x_{s2'} + x_{s2'')/2, \quad (7a)$$

$$z_{a1} = (z_{s1'} + z_{s1'')/2, \quad z_{a2} = (z_{s2'} + z_{s2'')/2. \quad (7b)$$

Thus, from Eqs. (5)–(7), one gets the following for the quasi-parallel case:

$$\begin{aligned} \sigma_T = & \frac{k_0^6}{16A\pi^5} \\ & \times \int \frac{D_{2'}(\hat{n}', \hat{n}^i) D_{2'}(\hat{n}', \hat{n}^i) D_{2''}^*(\hat{n}', \hat{n}^i) D_{1''}^*(\hat{n}', \hat{n}^i)}{(n_y^f - n_y')(n_y^f - n_y'')(n_y^i + n_y')(n_y^i + n_y'')} \\ & \times U(\mathbf{r}_{a1}) U(\mathbf{r}_{a2}) \exp\{jk_0[n_x^f x_{d2} \\ & - n_x'(0.5x_{d2} - 0.5x_{d1} + x_{a2} - x_{a1}) \\ & + n_x''(-0.5x_{d2} + 0.5x_{d1} + x_{a2} - x_{a1}) - n_x^i x_{d1}]\} \\ & \times \exp\{jk_0[n_z^f z_{d2} - n_z'(0.5z_{d2} - 0.5z_{d1} \\ & + z_{a2} - z_{a1}) + n_z''(-0.5z_{d2} + 0.5z_{d1} + z_{a2} - z_{a1}) \\ & - n_z^i z_{d1}]\} \exp\{jk_0[n_y^f(h_{2'} - h_{2'')}) \\ & - n_y'(h_{2'} - h_{1'}) + n_y''(h_{2''} - h_{1'') - n_y^i(h_{1'} - h_{1'')]\} \\ & \times \frac{dn_y' dn_z'}{(1 - n_y'^2 - n_z'^2)^{1/2}} \frac{dn_y'' dn_z''}{(1 - n_y''^2 - n_z''^2)^{1/2}} \\ & \times dx_{d1} dz_{d1} dx_{d2} dz_{d2} dx_{a1} dz_{a1} dx_{a2} dz_{a2}. \end{aligned} \quad (8)$$

For the quasi-parallel case [see Fig. 1(c)], the integrand in Eq. (8) becomes stationary as the points 1' and 1'' as

Fig. 1. (a) Double-scatter electromagnetic wave, (b) double-scatter intensity for two-dimensional random rough surfaces, (c) double-scatter quasi-parallel case, (d) double-scatter quasi-antiparallel case.

well as $2'$ and $2''$ approach each other. Thus, to simplify the 12-dimensional integral (8), we use the Taylor-series expansion for the heights at the pair of points $1', 1''$ and $2', 2''$ in terms of the heights and their derivatives at the midpoints (x_{a1}, z_{a1}) and (x_{a2}, z_{a2}) . Upon using Eqs. (6) and (7), we introduce the following approximations in Eq. (8):

$$h_{1'} = h_{a1} + (x_{d1}h_{xa1} + z_{d1}h_{za1})/2, \quad (9a)$$

in which

$$h_{a1} = h_y(x_{a1}, z_{a1}), \quad h_{xa1} = \partial h / \partial x, \quad (9b)$$

$$h_{za1} = \partial h / \partial z \text{ at } x = x_{a1} \text{ and } z = z_{a1}, \quad (9c)$$

$$h_{1''} = h_{a1} - (x_{d1}h_{xa1} + z_{d1}h_{za1})/2; \quad (9d)$$

thus

$$h_{1'} - h_{1''} = x_{d1}h_{xa1} + z_{d1}h_{za1}. \quad (9d)$$

Similar expressions are introduced in Eq. (8) for $h_{2'}$ and $h_{2''}$. The integration with respect to $x_{d1}x_{a1}$ is over the diamond-shaped area with corners at $(x_{d1} = 0, x_{a1} = l_x)$, $(x_{d1} = 2l_x, x_{a1} = 0)$, $(x_{d1} = 0, x_{a1} = -l_x)$, and $(x_{d1} = -2l_x, x_{a1} = 0)$. Similarly, diamond-shaped areas represent the limits of integration for $x_{d2}x_{a2}$, $z_{d1}z_{a1}$, and $z_{d2}z_{a2}$. Since $k_0l_x \gg k_0l_a \gg 1$ and $k_0l_z \gg k_0l_c \gg 1$ (l_c is the correlation length for the rough surface), the lim-

its of integration for the variables x_{d1} , x_{d2} , z_{d1} , and z_{d2} in Eq. (1) are assumed to be infinite.

The integral representation of the Dirac delta function is

$$\delta(h_x - h_{xs}) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp[ix_d(h_x - h_{xs})] dx_d. \quad (10)$$

On integration with respect to x_{d1} , x_{d2} , z_{d1} , and z_{d2} , the 12-dimensional integral in Eq. (8) reduces to an eight-dimensional integral containing the following product of four Dirac delta functions:

$$\begin{aligned} & \delta(h_{xa1} - h_{xa1s}) \delta(h_{xa2} - h_{xa2s}) \delta(h_{za1} - h_{za1s}) \\ & \times \delta(h_{za2} - h_{za2s}) \\ & = \delta(\nabla h_{a1} - \nabla h_{a1s}) \delta(\nabla h_{a2} - \nabla h_{a2s}), \end{aligned} \quad (11)$$

in which ∇ is the symbol for gradient and the slopes at the specular points (x_{a1s}, z_{a1s}) , and (x_{a2s}, z_{a2s}) are given by

$$h_{xa1s} = - \left(-n_x^i + \frac{n_x' + n_x''}{2} \right) / \left(-n_y^i + \frac{n_y' + n_y''}{2} \right), \quad (12a)$$

$$h_{xa2s} = - \left(-n_x^f + \frac{n_x' + n_x''}{2} \right) / \left(-n_y^f + \frac{n_y' + n_y''}{2} \right), \quad (12b)$$

$$h_{za1s} = -\left(-n_z^i + \frac{n_z' + n_z''}{2}\right) / \left(-n_y^i + \frac{n_y' + n_y''}{2}\right), \quad (12c)$$

$$h_{za2s} = -\left(-n_z^f + \frac{n_z' + n_z''}{2}\right) / \left(-n_y^f + \frac{n_y' + n_y''}{2}\right). \quad (12d)$$

Thus, in the high-frequency (physical optics) limit, the major contributions to the double-scatter cross sections come from the neighborhoods of the specular points. Equation (8) reduces to

$$\sigma_T^{PQ} = \frac{k_0^2}{\pi A} \sum_{R,S=V,H} \int \frac{D_2^{PS}(\hat{n}', \hat{n}') D_1^{SQ}(\hat{n}', \hat{n}') D_2^{*PR}(\hat{n}', \hat{n}') D_1^{*RQ}(\hat{n}', \hat{n}')}{(n_y^f - n_y')(n_y^f - n_y'')(n_y^i - n_y')(n_y^i - n_y'')} U(\mathbf{r}_{a1}) U(\mathbf{r}_{a2}) \delta(\nabla h_{a1} - \nabla h_{a1s}) \\ \times \delta(\nabla h_{a2} - \nabla h_{a2s}) \exp[jk_0(\mathbf{r}_{a1} - \mathbf{r}_{a2}) \cdot (\hat{n}' - \hat{n}'')] \frac{dn_y' dn_z' dn_y'' dn_z'' dx_{a1} dx_{a2} dz_{a1} dz_{a2}}{n_x'' n_x' [n_y^f - (n_y' + n_y'')/2]^2 [n_y^i - (n_y' + n_y'')/2]^2}, \quad (13)$$

where \mathbf{r}_{a1} and \mathbf{r}_{a2} are position vectors to the midpoints [Eqs. (7)], i.e.,

$$\mathbf{r}_{ai} = x_{ai} \hat{\mathbf{e}}_x + h_{ai} \hat{\mathbf{e}}_y + z_{ai} \hat{\mathbf{e}}_z \quad (i = 1, 2). \quad (14)$$

The vectors \hat{n}' and \hat{n}'' are defined in Eqs. (2). Furthermore, for $i = 1, 2$,

$$\nabla h_{ai}(x, z) = h_{xai} \hat{\mathbf{e}}_x + h_{zai} \hat{\mathbf{e}}_z,$$

$$\nabla h_{ais}(x, z) = h_{xais} \hat{\mathbf{e}}_x + h_{zais} \hat{\mathbf{e}}_z. \quad (15)$$

The statistical average of σ_T over the random heights h_{ai} and slopes ∇h_{ai} is obtained on multiplying Eq. (13) by the probability density functions for the heights and the slopes at the midpoints and integrating over the heights and the slopes. Thus Eq. (13) reduces to

$$\langle \sigma_T^{PQ} \rangle \approx \frac{k_0^2}{\pi A} P_2(\hat{n}') P_2(\hat{n}'') \sum_{P,Q=V,H} \int \left[\frac{D_2^{PS}(\hat{n}', \hat{n}') D_1^{SQ}(\hat{n}', \hat{n}') D_2^{*PR}(\hat{n}', \hat{n}') D_1^{*RQ}(\hat{n}', \hat{n}')}{(n_y^f - n_y')(n_y^f - n_y'')(n_y^i - n_y')(n_y^i - n_y'')} \right] \\ \times \exp[jk_0(\rho_{a1} - \rho_{a2}) \cdot (\hat{n}' - \hat{n}'')] \exp[-k_0^2 \langle h^2 \rangle (n_y' - n_y'')^2] p(\nabla h_{a1s}, \nabla h_{a2s}) [1 - P_2(|n_y'|)] \\ \times [1 - P_2(|n_y''|)] \frac{dn_y' dn_z' dn_y'' dn_z'' dx_{a1} dx_{a2} dz_{a1} dz_{a2}}{n_x'' n_x' [n_y^f - (n_y' + n_y'')/2]^2 [n_y^i - (n_y' + n_y'')/2]^2}. \quad (16a)$$

For the derivation of Eq. (16), it has been assumed that the distance between the midpoints of the pairs of points 1', 1'' and 2', 2'' (namely, $|\mathbf{r}_{a1} - \mathbf{r}_{a2}|$) is larger than the correlation length l_c of the surface height autocorrelation function, such that

$$\langle \exp[ik_0(n_y' - n_y'')(h_{a1} - h_{a2})] \rangle \\ \approx \langle \exp[ik_0(n_y' - n_y'')h_{a1}] \rangle \langle \exp[-ik_0(n_y' - n_y'')h_{a2}] \rangle \\ = |\chi^2[k_0(n_y' - n_y'')]|. \quad (16b)$$

When the distance between the midpoints is small compared with l_c , the elements of the four scattering matri-

ces D^{PQ} become vanishingly small for the quasi-parallel case ($\hat{n}' \approx \hat{n}''$), since $[(\hat{n}' + \hat{n}'') \cdot \nabla h_{a1}]$, $[(\hat{n}' + \hat{n}'') \cdot \nabla h_{a2}] \rightarrow 0$. Furthermore, in Eq. (16), the surface element scattering coefficients D^{PQ} are evaluated at the specular points, P_2 is the shadow function,³ and $P_2(\hat{n}')$ and $P_2(\hat{n}'')$ are the probabilities that the rough surface is not in the shadow for the incident and scattered waves, respectively, while $[1 - P_2(|n_y|)]$ is the probability that a double-scatter event will occur. Furthermore, for $i = 1, 2$,

$$\rho_{ai} = \mathbf{r}_{ai} - h_{ai} \mathbf{e}_y \quad (17a)$$

and $p(\nabla h_{a1s}, \nabla h_{a2s})$ is the probability density function of the slopes at specular points. In Eq. (16) a Gaussian probability density function with mean square height $\langle h^2 \rangle$ has been assumed for the height of the random rough surface. To integrate with respect to the horizontal components of the midpoint position vectors, we make the following transformations:

$$\rho_{a1} - \rho_{a2} \equiv \rho_{ad}, \quad (\rho_{a1} + \rho_{a2})/2 \equiv \rho_{aa}. \quad (17b)$$

The range of the integration variables x_{aa} and z_{aa} is $-l_x < x_{aa} < l_x$ and $-l_z < z_{aa} < l_z$. The integration with respect to x_{aa} and z_{aa} yields the radar footprint $A = 4l_x l_z$, since the integrand is independent of ρ_{aa} . Furthermore, the integration with respect to the components of ρ_{ad} (x_{ad} and z_{ad}) yields a product of two sinc functions,

since the range of the variables x_{ad} and z_{ad} is $-L_m \leq x_{ad} < L_m$ and $-L_m < z_{ad} < L_m$, respectively. Thus

$$\int_{-L_m}^{L_m} \int_{-L_m}^{L_m} \exp[jk_0 \rho_{ad} \cdot (\hat{n}' - \hat{n}'')] dx_{ad} dz_{ad} \\ = 2L_m \text{sinc}[k_0 L_m (n_x' - n_x'')] 2L_m \text{sinc}[k_0 L_m (n_z' - n_z'')], \quad (18)$$

in which L_m is the mean width of a typical depression on the rough surface.^{1,4,5} The above analytical procedures reduce the 12-dimensional integral (5) (not including averaging over the random heights and slopes at two differ-

ent points on the rough surface) into a tractable four-dimensional integral over the variables n_y' , n_y'' , n_z' , and n_z'' .

Upon changing the integration variables n_y' , n_y'' , n_z' , and n_z'' to the spherical coordinate variables θ and ϕ , one gets

$$\langle \sigma_{dp}^{PQ} \rangle = \frac{(2k_0 L_m)^2}{\pi} P_2(\hat{\mathbf{n}}^i) P_2(\hat{\mathbf{n}}^f) \sum_{R,S=V,H} \int \left[\frac{[D_{2'}^{PS}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i) D_{1'}^{SQ}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i) D_{2''}^{*PR}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i) D_{1''}^{*RQ}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i)]}{(n_y^f - n_y')(n_y^f - n_y'')(-n_y^i + n_y')(-n_y^i + n_y'')} \right] \\ \times \frac{p(h_{x1s} h_{x2s} h_{z1s} h_{z2s})}{[n_y^f - (n_y' + n_y'')/2]^2 [-n_y^i + (n_y' + n_y'')/2]^2} [1 - P_2(|n_y^i|)] [1 - P_2(|n_y^f|)] \\ \times \sin[k_0 L_m (n_x' - n_x'')] \text{sinc}[k_0 L_m (n_z' - n_z'')] \exp[-(h^2) k_0^2 (n_y' - n_y'')^2] \sin \theta' \sin \theta'' d\theta' d\theta'' d\phi' d\phi''. \quad (19)$$

It is useful to determine *a priori* the regions (defined by the four variables n_y' , n_y'' , n_z' , and n_z'') that contribute most significantly to the like-polarized ($P = Q = V$ or H) and cross-polarized ($P \neq Q = V$ or H) bistatic double-scatter cross sections. In view of the two sinc functions and the characteristic function $\chi[k_0(n_y' - n_y'')h]$ in the integral expression for the double-scatter cross sections [Eq. (19)], the major contribution to the integral is from the region $\hat{\mathbf{n}}^i \rightarrow \hat{\mathbf{n}}^f$ (quasi parallel). Furthermore, because of the shadow function $(1 - P_2)$, when these quasi-parallel paths are also quasi horizontal ($n_y' \approx 0$, $n_y'' \approx 0$), the value of the integrand in Eq. (19) peaks. To facilitate the numerical integration of relation (16), in view of the integrable singularity associated with $n_x' n_x''$ in the denominator of relation (16), the following transformations to polar coordinates are implemented for both $\hat{\mathbf{n}}^i$ and $\hat{\mathbf{n}}^f$:

$$n_x = \sin \theta \cos \phi, \quad n_y = \cos \theta, \quad n_z = \sin \theta \sin \phi, \\ 0 < \theta < \pi, \quad \phi_0 < \phi < 2\pi + \phi_0, \quad (20)$$

where ϕ_0 is an arbitrary constant. The product of the Jacobians of these transformations is

$$J' J'' = \sin^2 \theta' \cos \phi' \sin^2 \theta'' \cos \phi''. \quad (21a)$$

The ranges of the variables are $0 < \theta'$, $\theta'' < \pi$ and $\phi_0 < \phi'$, $\phi'' < 2\pi + \phi_0$. For the quasi-parallel case, $\phi_0 = 0$ is a suitable choice. Thus

$$dn_y' dn_y'' dn_z' dn_z'' / n_x' n_x'' = \sin \theta' \sin \theta'' d\theta' d\theta'' d\phi' d\phi''. \quad (21b)$$

Since the scattering coefficients D^{PQ} vanish for grazing incident and scatter angles, there are no singularities that are due to the product appearing below the scattering coefficients D^{PQ} in Eq. (19). For $n_y^i \rightarrow 0$, $n_y^f \rightarrow 0$ grazing incident and scatter angles, the shadow functions $P_2(\hat{\mathbf{n}}^i)$ and $P_2(\hat{\mathbf{n}}^f)$ vanish. Furthermore, when $n_y' \rightarrow 0$ and $n_y'' \rightarrow 0$, the probability for a double-scatter event $(1 - P_2) \rightarrow 1$. Thus Eq. (19) is not singular when the product appearing below the probability density function for the slopes (at the specular points) vanishes. It takes 1–2 CPU hours to evaluate the four-dimensional integrals in Eq. (19) for all four cross sections σ^{PQ} on a Silicon Graphics Computer model 4D/380VGX in the Center for Electro-Optics at the University of Nebraska-Lincoln. To

make sure that the integration subroutine does not miss the very narrow region around $\theta'' \approx \theta' \approx \pi/2$ and $\phi'' \approx \phi'$, where the integrand peaks for the quasi-parallel case, and to reduce the regions of integration in Eq. (19), we subdivide the limits of integration ($0 \leq \theta'$, $\theta'' \leq \pi$ and $0 < \phi'$, $\phi'' \leq 2\pi$) as follows for the quasi-parallel

case:

$$0 \leq \theta'' \leq \theta', \quad \theta' \leq \theta'' \leq \pi, \\ 0 \leq \phi'' \leq \phi', \quad \phi' \leq \phi'' \leq 2\pi. \quad (22a)$$

It can be shown that if the medium below the rough interface [$y < h(x, z)$; μ_1 , ϵ_1] is finitely conducting, the complex value of the integral $\langle \sigma_{dp}^{PQ} \rangle$ corresponding to $0 \leq \theta'' \leq \theta'$ is equal to the complex conjugate of the value of the integral $\langle \sigma_{dp}^{PQ} \rangle$ corresponding to $\theta' \leq \theta'' \leq \pi$. Thus it is necessary to evaluate only the real part of the integral [Eq. (19)] over half the total region of integration in Eq. (19), since

$$\langle \sigma_{dp}^{PQ} \rangle = \langle \sigma_1^{PQ} \rangle + \langle \sigma_2^{PQ} \rangle = 2 \text{Re} \langle \sigma_1^{PQ} \rangle. \quad (22b)$$

As noted above, this scheme not only increases the accuracy of the numerical integration of $\langle \sigma_{dp}^{PQ} \rangle$ (since the most significant part of the integral is never missed) but also reduces the amount of computation needed to evaluate the integrals. However, no attempt has been made to parallelize the computer codes in order to decrease the computation time for parallel-processing supercomputers.

For the quasi-antiparallel double-scatter paths between points 1' and 2' and points 1'' and 2'' [see Fig. 1(d)], the following transformations of variables are used in Eq. (5):

$$x_{d1} = x_{s1'} - x_{s2''}, \quad x_{d2} = x_{s2'} - x_{s1''}, \quad (23a)$$

$$z_{d1} = z_{s1'} - z_{s2''}, \quad z_{d2} = z_{s2'} - z_{s1''}, \quad (23b)$$

$$x_{a1} = (x_{s1'} + x_{s2''})/2, \quad x_{a2} = (x_{s2'} + x_{s1''})/2, \quad (23c)$$

$$z_{a1} = (z_{s1'} + z_{s2''})/2, \quad z_{a2} = (z_{s2'} + z_{s1''})/2. \quad (23d)$$

Furthermore, in addition to Eqs. (9a) and (9b) (unchanged), Eqs. (9c) and (9d) are replaced by

$$h_{2''} = h_{a2} - (x_{d2} h_{xa2} + z_{d2} h_{za2})/2; \quad (24a)$$

thus

$$h_{1'} - h_{2''} = x_{d1} h_{xa1} + z_{d1} h_{za1}. \quad (24b)$$

Equations (17) (unchanged) are also used to reduce the 12-dimensional integral into a four-dimensional integral. Thus, on following the same procedures as those for the quasi-parallel case, one gets the following integral expres-

sion for the (high-frequency) quasi-antiparallel ($n'_a < 0$, $n''_a > 0$ or $n'_a > 0$, $n''_a < 0$) double-scatter cross sections:

$$\begin{aligned} \langle \sigma_{da}^{PQ} \rangle = & \frac{(2k_0 L_m)^2}{\pi} P_2(\hat{\mathbf{n}}^i) P_2(\hat{\mathbf{n}}^f) \sum_{R,S=V,H} \int \left[\frac{D_{2'}^{PS}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i) D_{1'}^{SQ}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i) D_{2''}^{*PR}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i) D_{1''}^{*RQ}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i)}{(n_y^f - n_y^i)(n_y^f - n_y^i)(-n_y^i + n_y^i)(-n_y^i + n_y^i)} \right] \\ & \times p(h_{xa1s}, h_{xa2s}, h_{za1s}, h_{za2s}) 16/(n_y^f - n_y^i + n_y^i - n_y^i) (n_y^f - n_y^i - n_y^i + n_y^i)^2 [1 - P_2(|n_y^i|)] [1 - P_2(|n_y^i|)] \\ & \times \text{sinc}[k_0 L_m(n_x^f + n_x^i - n_x^i - n_x^i)] \text{sinc}[k_0 L_m(n_z^f + n_z^i - n_z^i - n_z^i)] \exp[-(h^2)k_0^2(n_y^f - n_y^i - n_y^i + n_y^i)^2] \\ & \times \sin \theta' \sin \theta'' d\theta' d\theta'' d\phi' d\phi''. \end{aligned} \quad (25a)$$

For the quasi-antiparallel case, the arguments of the sinc functions and the characteristic function vanish (and the integrand peaks) when $\hat{\mathbf{n}}' = -\hat{\mathbf{n}}''$ only for backscatter ($\hat{\mathbf{n}}^f = -\hat{\mathbf{n}}^i$). In Eq. (25a) the vectors $\hat{\mathbf{n}}'$ and $\hat{\mathbf{n}}''$ are expressed in terms of their polar coordinates as in Eqs. (20), except that for the quasi-antiparallel case, $\hat{\mathbf{n}}' = -\hat{\mathbf{n}}''$ ($\theta'' = \pi - \theta'$, $\phi'' = \phi' + \pi$). In relations (22a), it is convenient to choose $\phi_0 = -\pi$ for ϕ' and $\phi_0 = 0$ for ϕ'' for the quasi-antiparallel case, such that $-\pi \leq \phi' < \pi$ and $0 \leq \phi'' \leq 2\pi$. In this case, the limits of integration are subdivided as follows:

$$\begin{aligned} 0 \leq \theta'' \leq \pi - \theta', \quad \pi - \theta' \leq \theta'' \leq \pi, \\ 0 \leq \phi'' \leq \phi' + \pi, \quad \phi' + \pi \leq \phi'' \leq 2\pi. \end{aligned} \quad (25b)$$

The slopes at the specular points for the quasi-antiparallel case are given by

$$h_{xa1s} = -(n_x^f - n_x^i + n_x^i - n_x^i)/(n_y^f - n_y^i + n_y^i - n_y^i), \quad (26a)$$

$$h_{xa2s} = -(n_x^f - n_x^i + n_x^i - n_x^i)/(n_y^f - n_y^i + n_y^i - n_y^i), \quad (26b)$$

$$h_{za1s} = -(n_z^f - n_z^i + n_z^i - n_z^i)/(n_y^f - n_y^i + n_y^i - n_y^i), \quad (26c)$$

$$h_{za2s} = -(n_z^f - n_z^i + n_z^i - n_z^i)/(n_y^f - n_y^i + n_y^i - n_y^i), \quad (26d)$$

The sharp enhancement in the backscatter direction ($-\hat{\mathbf{n}}^i = \hat{\mathbf{n}}^f$) is associated with the quasi-antiparallel ($\hat{\mathbf{n}}^f \approx -\hat{\mathbf{n}}''$) double-scatter cross section [Eq. (25a)].^{1,4,6,7} Note the differences in the expressions for the slopes at the specular points for the quasi-parallel and quasi-antiparallel cases (12) and (26), respectively. Equations (12) and (26) can be readily interpreted. The vectors normal to the surface at the specular points 1', 1'', 2', and 2'' are $\hat{\mathbf{n}}_{s1'}$, $\hat{\mathbf{n}}_{s1''}$, $\hat{\mathbf{n}}_{s2'}$, and $\hat{\mathbf{n}}_{s2''}$, respectively, where

$$\begin{aligned} \hat{\mathbf{n}}_{s1'} &= \hat{\mathbf{n}}' - \hat{\mathbf{n}}^i, & \hat{\mathbf{n}}_{s1''} &= \hat{\mathbf{n}}'' - \hat{\mathbf{n}}^i, \\ \hat{\mathbf{n}}_{s2'} &= \hat{\mathbf{n}}^f - \hat{\mathbf{n}}^i, & \hat{\mathbf{n}}_{s2''} &= \hat{\mathbf{n}}^f - \hat{\mathbf{n}}^i. \end{aligned} \quad (27)$$

For the quasi-parallel case $\hat{\mathbf{n}}' \approx \hat{\mathbf{n}}''$, the vectors $\hat{\mathbf{n}}_{s1'}$ and $\hat{\mathbf{n}}_{s2'}$ are also quasi parallel to the vectors $\hat{\mathbf{n}}_{s1''}$ and $\hat{\mathbf{n}}_{s2''}$, respectively, and the slopes at the midpoints between 1', 1'' and 2', 2'' [see Fig. 1(c)] are given by the vectors

$$\hat{\mathbf{n}}_{sdp1} = (\hat{\mathbf{n}}_{s1'} + \hat{\mathbf{n}}_{s1''})/2, \quad \hat{\mathbf{n}}_{sdp2} = (\hat{\mathbf{n}}_{s2'} + \hat{\mathbf{n}}_{s2''})/2, \quad (28)$$

corresponding to the slopes in Eqs. (12). Similarly, for the antiparallel case $\hat{\mathbf{n}}' \approx -\hat{\mathbf{n}}''$, the slopes at the midpoints between 1', 2'' and 1'', 2' [see Fig. 1(d)] are given by the components of the vectors

$$\hat{\mathbf{n}}_{sdp1} = (\hat{\mathbf{n}}_{s1'} + \hat{\mathbf{n}}_{s2''})/2, \quad \hat{\mathbf{n}}_{sdp2} = (\hat{\mathbf{n}}_{s1''} + \hat{\mathbf{n}}_{s2'})/2, \quad (29)$$

corresponding to the slopes in Eqs. (26). Furthermore, the integrand in Eq. (19) peaks when the pairs of vectors $\hat{\mathbf{n}}_{s1'}$, $\hat{\mathbf{n}}_{s1''}$ and $\hat{\mathbf{n}}_{s2'}$, $\hat{\mathbf{n}}_{s2''}$ are parallel to each other, namely,

$$\hat{\mathbf{n}}_{sdp} = \hat{\mathbf{n}}_{s1'} - \hat{\mathbf{n}}_{s1''} = \hat{\mathbf{n}}_{s2'} - \hat{\mathbf{n}}_{s2''} = \hat{\mathbf{n}}' - \hat{\mathbf{n}}'' = 0. \quad (30)$$

The integrand in Eq. (25a) peaks when the pairs of vectors $\hat{\mathbf{n}}_{s1'}$, $\hat{\mathbf{n}}_{s2''}$, and $\hat{\mathbf{n}}_{s1''}$, $\hat{\mathbf{n}}_{s2'}$, are parallel, namely,

$$\begin{aligned} \hat{\mathbf{n}}_{sda} &= \hat{\mathbf{n}}_{s1'} - \hat{\mathbf{n}}_{s2''} = \hat{\mathbf{n}}_{s1''} - \hat{\mathbf{n}}_{s2'} \\ &= \hat{\mathbf{n}}' + \hat{\mathbf{n}}'' - \hat{\mathbf{n}}^f - \hat{\mathbf{n}}^i \rightarrow 0. \end{aligned} \quad (31)$$

Note that for Eq. (30) to be satisfied, the paths must be parallel; however, for Eq. (31) to be satisfied, the paths must be antiparallel for backscatter only. This distinction between the quasi-parallel case and the quasi-antiparallel case explains why the enhanced backscatter is associated only with the quasi-antiparallel case.

For backscatter at normal incidence, the major contributions to the double-scatter cross sections are associated with the quasi-horizontal paths between points 1 and 2 [see Fig. 1(d)], and the slopes at the stationary points are approximately $\pm 45^\circ$. The integrands in the final expressions for the double-scatter cross sections [Eqs. (19) and (25)] peak for a very small range of angles at which $\hat{\mathbf{n}}'$ and $\hat{\mathbf{n}}''$ are quasi horizontal ($n_y^f \approx 0$ and $n_y^i \approx 0$), as a result of the presence of $1 - \bar{P}_2$ in the integrand. The characteristic functions

$$\chi[k_0(n_y^f - n_y^i)] = \exp[-(h^2)k_0^2(n_y^f - n_y^i)^2/2],$$

$$\begin{aligned} \chi[k_0(n_y^f + n_y^i - n_y^i - n_y^i)] \\ = \exp[-(h^2)k_0^2(n_y^f + n_y^i - n_y^i - n_y^i)^2/2] \end{aligned}$$

in Eqs. (19) and (25) peak for $(n_y^f - n_y^i) \rightarrow 0$ (quasi parallel) and $(n_y^f + n_y^i - n_y^i - n_y^i) \rightarrow 0$ (quasi antiparallel and backscatter), respectively. For the illustrative examples, Eqs. (19) and (25) are used to evaluate the bi-static double-scatter cross sections. The corresponding high-frequency single-scatter cross sections are

$$\begin{aligned} \langle \sigma_s^{PQ} \rangle &= 4\pi |D^{PQ}(\hat{\mathbf{n}}^f, \hat{\mathbf{n}}^i)|^2 p(h_{xs}, h_{zs})/(n_y^f - n_y^i)^4, \\ P &= Q, \quad \langle \sigma_s^{PQ} \rangle = 0, \quad P \neq Q, \end{aligned} \quad (32)$$

since the incident waves are not depolarized at the specular points in the plane of incidence.

3. ILLUSTRATIVE EXAMPLES

The incoherent single- and double-scatter cross sections (quasi parallel+quasi antiparallel), as well as the total (single+double) cross sections, for two-dimensional rough surfaces are plotted in Figs. 2-10 as functions of the scatter angles $\theta^f \cos \phi^f$ (where $\phi^f = 0, \pi$). The two-dimensional rough surface is assumed to be coated with gold permittivity $\epsilon_r = -9.888312 - j1.051766$ at $\lambda = 0.633 \mu\text{m}$. The incident angles are $\theta^i = 10^\circ$, $\phi^i = 0$. The Rayleigh roughness parameter is $\beta = 4k_0^2 \langle h^2 \rangle$. In Figs. 2-4, the single-scatter cross sections are plotted as functions of the scatter angles $\theta^f \cos \phi^f$, $\phi^f = 0$ and π . In Fig. 2 the polarizations of the incident and scattered waves are vertical (parallel). The Rayleigh roughness parameter $\beta = 4k_0^2 \langle h^2 \rangle$ varies from 10 to 394, and the mean square slope is $mss = 0.5$. The single-scatter incoherent cross sections are insensitive to $\langle h^2 \rangle$, since, for the entire range of the parameters considered, $\beta \gg 1$. They are sensitive to $\langle h^2 \rangle$ when $\beta < 1$. They are proportional to $\langle h^2 \rangle$ for $\beta \ll 1$ where the coherent scatter cross sections are not small. For $\beta \gg 1$ the coherent cross sections are negligible.

In Fig. 3 the polarizations of the incident and scattered waves are vertical (parallel), and the mss varies from 0.25 to 1.0 and $\beta = 394$. For the range of parameters consid-

Fig. 2. Single-scatter vertical-to-vertical radar cross section. Mean square height (Rayleigh parameter β) is the variable parameter $10 \leq \beta \leq 394$. The mean square slope (mss) value is 0.5. The following parameters apply to Figs. 2-10: incident angle of 10° , relations permittivity of $-9.888312/j1.051766$, and wavelength of $0.633 \mu\text{m}$.

Fig. 3. Single-scatter vertical-to-vertical radar cross section. Mean square slope (mss) is the variable parameter, and the curves from top to bottom correspond to mss values of 0.25, 0.4, 0.5, 0.65, 0.75, 0.85, and 1.0. The value of β is 394.

Fig. 4. Single-scatter like-polarized radar cross section for vertical to vertical (lower curve) and horizontal-to-horizontal (upper curve) polarization. The mss and β values are 0.5 and 394, respectively.

Fig. 5. Double-scatter radar cross section. Mean square height (Rayleigh parameter β) is the variable parameter (quasi-parallel and quasi-antiparallel contributions added). The polarization is vertical to vertical. The mss value is 0.5. Lowest curve, $\beta = 10$. Data saturate as β increases.

ered, the single-scatter cross sections decrease as the mss increases, while the double-scatter cross sections increase with increasing mss . As the mss becomes larger than unity, the values of both the single- and double-scatter cross sections saturate.

In Fig. 4 the single-scatter cross sections are plotted for both vertical (parallel) and horizontal (perpendicular) polarizations. The results indicate that for the given values of $\beta = 394$ and $mss = 0.5$, the single-scatter cross sections are practically the same for both like polarizations.

In Figs. 5-7 the double-scatter cross sections are plotted as functions of the scatter angles $\theta^f \cos \phi^f$, $\phi^f = 0$ or π . These three illustrations correspond to the cases considered in Figs. 2-4.

In Fig. 5 the polarizations of the incident and scatter waves are vertical (parallel). The roughness parameter β increases from 10 to 394, and $mss = 0.5$. The double-scatter cross sections (unlike the single-scatter cross sections) are sensitive to variations in β . The cross sections increase as β increases, and they practically merge for $\beta > 100$. For $\beta \gg 100$ higher-order multiple-scatter cross section are not negligible.

In Fig. 6 the polarizations of the incident and scattered waves are vertical (parallel). The roughness parameter $\beta = 394$, and the mss varies from 0.25 to 1. Both β and the mss are dimensionless quantities, since the slope is

dimensionless and $k_0 = 2\pi/\lambda$ is measured in units of inverse meters. The double-scatter cross sections are more sensitive to variations in mss than to those in β . Unlike the single-scatter cross sections, the double-scatter cross sections increase rather than decrease as mss increases, and they begin to merge for $mss > 0.75$. The level of the enhanced backscatter increases as both the roughness parameter β and mss increase. However, they merge for $\beta > 100$ and $mss > 0.75$. The angular width of the backscatter cross sections decreases as β increases; however, the angular width is practically insensitive to variations in the mss for the range of parameters considered.

In Fig. 7 all four like- and cross-polarized double-scatter cross sections are plotted as functions of the scatter angles $\theta^f \cos \phi^f$, $\phi^f = 0$. The level and the angular width of the backscatter enhancement for all four cross sections are practically the same, except that the values of the cross-polarized cross sections decrease somewhat faster as $\theta^f \rightarrow 90^\circ$ (grazing angles). For the illustrative examples, the first and second letters ($P = V, H$; $Q = V, H$) correspond to the polarizations of the scattered and incident waves, respectively.

In Figs. 8–10, the total (single+double) scatter cross sections are plotted as functions of the scatter angles. These three illustrations correspond to the cases considered in Figs. 2–4 and 5–7. In Fig. 8 the total cross sec-

Fig. 6. Double-scatter radar cross section. The variable parameter is the mss (quasi-parallel and quasi-antiparallel contributions added). The polarization is vertical to vertical. The value of β is 394. Lowest curve, $mss = 0.25$. Data saturate as mss increases.

Fig. 7. Double-scatter radar cross sections for both like-polarized and both cross-polarized cases (quasi-parallel and quasi-antiparallel contributions added). The mss and β values are 0.5 and 394.105, respectively. Cross-polarized data are lower near grazing angles.

Fig. 8. Single- and double-scatter radar cross sections added. The variable parameter is β . The polarization is vertical to vertical. The mss value is 0.5. Lowest curve, $\beta = 10$. Data saturate as β increases.

Fig. 9. Single- and double-scatter radar cross sections added. The variable parameter is the mss , and the curves from top to bottom correspond to mss values of 0.25, 0.4, 0.5, 0.65, 0.75, 0.85, and 1.0. The value of β is 394. The polarization is vertical to vertical.

Fig. 10. Single- and double-scatter radar cross sections added for both like-polarized and both cross-polarized cases. The mss and β values are 0.5 and 394, respectively. Upper curves, HH followed by VV. Lowest curves, VH and HV merge.

tion, for the vertically polarized case, is plotted with β as the variable parameter, from $\beta = 10$ to $\beta = 394$, while $mss = 0.5$. The total scatter cross sections increase as β increases, and the results merge for $\beta > 50$. The angular width of the enhancement decreases as β increases. As noted above, the results saturate for $\beta \gg 1$.

In Fig. 9 the total cross sections for the vertically polarized case are plotted as functions of the scatter angles, with mss as the variable parameter, from $mss = 0.25$ to

$mss = 1.0$. For the cases considered, the total cross sections decrease as the mss increases because the contributions of the single-scatter cross sections dominate the results. The level of the backscatter enhancement increases as mss increases. However, the angular width of the enhancement does not vary significantly with changing mss . Also, as noted above, the results saturate for mss greater than unity.

In the last illustration, Fig. 10, the total scatter cross sections are plotted for all four (like and cross) polarizations. The fixed parameters are $\beta = 394$ and $mss = 0.5$. The like-polarized cross sections (VV and HH) are significantly larger than the corresponding cross-polarized cross sections (VH and HV). This is because the stationary-phase (high-frequency) approximations for the cross-polarized, single-scatter cross sections are negligible for scatter angles in the plane of incidence.^{1,4,5} At the specular points in the plane of incidence ($\phi^f = 0, \pi$), the scattered waves are not depolarized.⁸ For scattering out of the incident plane, the scattered waves do depolarize. This results in nonvanishing cross-polarized, double-scatter cross sections, even in the plane of incidence.⁹ There are two mechanisms for the generation of the cross-polarized, double-scatter cross sections. Schematically, these are given by

$$\begin{aligned} V \rightarrow V \rightarrow H, & \quad V \rightarrow H \rightarrow H, \\ H \rightarrow H \rightarrow V, & \quad H \rightarrow V \rightarrow V. \end{aligned}$$

In the above the first letter corresponds to the polarization of the incident wave, the second is the polarization of the single-scatter wave, and the third is the polarization of the double-scatter wave.

4. CONCLUSIONS

The results for the double-scatter radar cross sections exhibit sharp enhancements in the backscatter direction at normal and oblique incident angles. This sharp enhancement is associated with the quasi-antiparallel double-scatter path. The height and the width of the peak in the backscatter direction depend on the mean square height and slope of the two-dimensional random rough surface. The high-frequency approximations make the computations numerically tractable; however, the polarization dependence of the cross section is less obvious.^{1,4}

Abstract

We consider the use of high resolution array processing methods for detecting and localizing near-field extended targets for measurement geometries in which an array of electromagnetic receivers observes the fields scattered by the objects in response to a plane wave illumination. The algorithms presented here modify the conventional direction finding array processing techniques and use the spatial complexities of fields to determine both the range and the bearing of the targets in the region of interest. In contrast to previous source localization problems, we employ electromagnetic scattering models parameterized explicitly in terms of the target positions and which account for all multiple scattering effects.

These models play an integral role in allowing us to compute explicitly the analytical expressions for the Cramér-Rao bounds (CRB) for position estimates. The Cramér-Rao bound gives the lower bound for the estimates, and thus, specifies the lowest possible error variance that can be attained with an unbiased estimator. The theoretical Cramér-Rao bounds are then verified using Monte-Carlo simulated error variances.

1 Introduction

Non-invasive detection and localization of objects in the near field of a receiver array have been of interest to many researchers in recent years. Some of the most promising application areas for this technology include landmine remediation, where relatively small metallic or plastic objects are located a few centimeters from the sensors, and hazardous waste remediation, where relatively large metallic objects (eg. steel metal drums) are located on the order of meters from the sensor array [1–3]. In this paper we consider a form of this problem shown in Fig. 1. A plane wave illuminates the region of interest assumed to be a homogeneous, possibly lossy medium containing one or more targets located in the near field of an array of receivers. The goal of the processing is the localization of objects with known structures.

The inherent array structure of the measurement geometry suggests that high resolution array processing techniques [4, 5] quite popular in the signal processing community would be well suited for the near-field detection problem. Typically, these techniques assume the targets are in the far field of the array so that the measured wavefronts are all planar in nature. The goal then is to determine the directions of arrival (DOA) of these wavefronts to characterize the bearing angles of the associated targets. In the case of near field target localization however, we must process scattered field data with distinctly non-planar wavefronts to determine both the range and the bearing angles of the objects. For far field range and bearing angle estimation problems, the matched field processing (MFP) approach has been successfully used for localization of typically point sources in ocean acoustics [6] and stratospherical electromagnetics [7]. MFP is an array processing technique that uses the spatial complexities of the fields to localize sources, and thus allows for estimation of both the range and the bearing of the objects.

In terms of near-field source localization, previous work has been concentrated on independently

radiating point sources [8–12] and the localization of a single extended object of unknown size and material [13]. The coherent source issue in near field localization is also dealt with in [9]. In [8,9], independent, spherical sound and noise sources are located using MUSIC based array processing methods. In [10] and [11], a similar near-field source localization scenario is considered, and performance bounds for coordinate estimates were derived for MUSIC and higher order ESPRIT based algorithms, respectively. Localization of distributed sources is reported in [14] where Valaee et al. introduced a MUSIC-based algorithm that parametrically localizes far field sources modeled with bell shaped distributions characterized by their peak position and 3 dB beamwidth. Finally, in [13] the authors employ a T-matrix type forward model as the basis for a non-linear least squares parameter estimation approach to determine the location, size, and material properties of a single object in the field of view of an array.
